Note: The authors have worked to ensure that all information in this book is accurate at the time of publication and consistent with general psychiatric and medical standards, and that information concerning drug dosages, schedules, and routes of administration is accurate at the time of publication and consistent with standards set by the U.S. Food and Drug Administration and the general medical community. As medical research and practice continue to advance, however, therapeutic standards may change. Moreover, specific situations may require a specific therapeutic response not included in this book. For these reasons and because human and mechanical errors sometimes occur, we recommend that readers follow the advice of physicians directly involved in their care or the care of a member of their family.

Books published by American Psychiatric Association Publishing represent the findings, conclusions, and views of the individual authors and do not necessarily represent the policies and opinions of American Psychiatric Association Publishing or the American Psychiatric Association.

Claes Wahlestedt, M.D., Ph.D.

Mark M. Rasenick, Ph.D.

Jiang-Zhou Yu, M.D., Ph.D.

Zane Zeier, Ph.D.

2 Neurotransmitters, Receptors, and Transporters

Kelly A. Berg, Ph.D.

William P. Clarke, Ph.D.

Lynette C. Daws, Ph.D.

Alan Frazer, Ph.D.

Milena Girotti, Ph.D.

Daniel J. Lodge, Ph.D.

3 Genetics and Epigenetics

Jessica Keverne, Ph.D.

Darina Czamara, Ph.D.

Elisabeth B. Binder, M.D., Ph.D.

4 Psychoneuroendocrinology

Luca Sforzini, M.D.

Frances Isabella Weston, B.Sc.

Carmine Maria Pariante, M.D., Ph.D., FRCPsych

5 Brain-Immune System Interactions

Firdaus S. Dhabhar, Ph.D.

Charles L. Raison, M.D.

Andrew H. Miller, M.D.

6 Pharmacokinetics, Pharmacodynamics, and Pharmacogenomics

Joseph F. Goldberg, M.D.

Appendix: Pharmacokinetic Parameters of Specific Medications

7 Neuroimaging and Psychiatry

Martin P. Paulus, M.D.

Salvador Guinjoan, M.D., Ph.D.

8 Personalized Medicine in Psychiatry

Giampaolo Perna, M.D., Ph.D.

Alessandra Alciati, M.D.

Charles B. Nemeroff, M.D., Ph.D.

9 Machine Learning in Psychopharmacology

Isaac R. Galatzer-Levy, Ph.D.

Anzar Abbas, Ph.D.

PART II

Classes of Psychiatric Treatments

Antidepressants and Anxiolytics

10 Monoamine Oxidase Inhibitors

K. Ranga Rama Krishnan, M.D.

11 Tricyclic and Tetracyclic Drugs

J. Craig Nelson, M.D.

12 Fluoxetine and Fluvoxamine

Elias Aboujaoude, M.D., M.A.

Jerrold F. Rosenbaum, M.D.

Dawn F. Ionescu, M.D.

Lorrin M. Koran, M.D.

13 Sertraline and Paroxetine

Jonathon R. Howlett, M.D.

Alan F. Schatzberg, M.D.

14 Citalopram and Escitalopram

Richard C. Shelton, M.D.

15 Trazodone and Nefazodone

Robert N. Golden, M.D.

Karon Dawkins, M.D.

Linda Nicholas, M.D.

16 Vortioxetine

Charles-Yoland Desfosses, M.D. Pierre Blier, M.D., Ph.D.

17 Mirtazapine

Alan F. Schatzberg, M.D.

18 Bupropion

Keri A. Stevenson, M.D.

David V. Hamilton, M.D., M.A.

Anita H. Clayton, M.D.

19 Venlafaxine and Desvenlafaxine

Michael E. Thase, M.D.

20 Duloxetine, Milnacipran, and Levomilnacipran

Manish K. Jha, M.D.

Taryn L. Mayes, M.S.

Madhukar H. Trivedi, M.D.

21 Ketamine and Esketamine

David S. Mathai, M.D.

Sanjay J. Mathew, M.D.

22 Benzodiazepines

David V. Sheehan, M.D., M.B.A., DLFAPA, FACPsych

23 Buspirone

Donald S. Robinson, M.D.

Karl Rickels, M.D.

Julie Farrington, M.D.

24 Brexanolone and Other Neurosteroids

Riah Patterson, M.D.

Holly Krohn, M.P.H.

Samantha Meltzer-Brody, M.D., M.P.H.

Antipsychotics

25 Classic Antipsychotic Medications

Henry A. Nasrallah, M.D.

Rajiv Tandon, M.D.

26 Clozapine

Yvonne S. Yang, M.D., Ph.D.

Stephen R. Marder, M.D.

27 Olanzapine

Jacob S. Ballon, M.D., M.P.H.
Julio C. Nunes, M.D.
Khalid Salaheldin, M.D.

28 Quetiapine
Peter F. Buckley, M.D.
Adriana E. Foster, M.D.

29 Risperidone and Paliperidone
Leonardo V. Lopez, M.D.
Michele Hill, MRCPsych
Donald C. Goff, M.D.

30 Aripiprazole and Brexpiprazole
Nikolajs K. Birze, M.D.
Chloe J. Yuan, M.D.
Erica C. Garcia-Pittman, M.D., FAPA, DFAAGP

31 Ziprasidone and Asenapine
John W. Newcomer, M.D.
Jared Lipsey, B.Sc.
Martin T. Strassnig, M.D.
Leslie Citrome, M.D., M.P.H.

32 Iloperidone
Peter F. Buckley, M.D.
Adriana E. Foster, M.D.

33 Lurasidone
Philip D. Harvey, Ph.D.

34 Cariprazine
Leslie Citrome, M.D., M.P.H.

35 Pimavanserin
Jeffrey Cummings, M.D., Sc.D.(HS)

36 Management of Psychiatric Medication-Induced Movement Disorders

Laura Marsh, M.D.

Drugs for Treatment of Bipolar Disorder

37 Lithium

Jorge Almeida, M.D., Ph.D.
David Spelber, M.D.
Tawny Smith, Pharm.D.

38 Valproate

Robert M.A. Hirschfeld, M.D.
Charles L. Bowden, M.D.

39 Carbamazepine, Oxcarbazepine, and Eslicarbazepine

Robert M. Post, M.D.
Po W. Wang, M.D.
Terence A. Ketter, M.D.

40 Gabapentin and Pregabalin

Mark A. Frye, M.D.
Katherine Marshall Moore, M.D.
Alan F. Schatzberg, M.D.

41 Lamotrigine

Keming Gao, M.D., Ph.D.
Joseph R. Calabrese, M.D.

42 Topiramate

Susan L. McElroy, M.D. 1109
Anna I. Guerdjikova, Ph.D., LISW, CCRC
Francisco Romo-Nava, M.D., Ph.D.

Other Agents

43 Agents for Neurocognitive Disorders

Gayle Ayers, D.O.

Frank W. Brown, M.D.

44 Sedative-Hypnotics

Seiji Nishino, M.D., Ph.D.

Taisuke Ono, M.D., Ph.D.

Naoya Nishino, M.D.

Noriaki Sakai, D.V.M., Ph.D.

Emmanuel Mignot, M.D., Ph.D.

45 Psychostimulants and Wakefulness-Promoting Agents

Charles DeBattista, D.M.H., M.D.

46 Electroconvulsive Therapy and Other Neuromodulation Therapies

William M. McDonald, M.D.

Thomas W. Meeks, M.D.

W. Vaughn McCall, M.D., M.S.

Charles F. Zorumski, M.D.

Introduction

In 1996, we published the first edition of the *Textbook of Psychopharmacology*, which was generally acknowledged as an immediate success, and we are delighted that the sixth edition of *The American Psychiatric Association Publishing Textbook of Psychopharmacology* is now being published. The field has grown greatly in the past 25-plus years, with amazing advances in neuroscience, psychopharmacology, and brain stimulation therapies. Commensurate with this growth, we have with each edition tried to present the most salient information both from basic neuroscience as it relates to the pathogenesis and pathophysiology underlying psychiatric disorders and from basic and clinical psychopharmacology. Each successive edition has understandably become larger as we have attempted to keep pace with the ever-growing body of knowledge in the field. The *Textbook* now has more than 160 authors--including more than 75 new contributors. It has 12 all-new chapters, and it is fully aligned with the revised DSM-5-TR classification. This Sixth Edition is published in two volumes.

The opening section in Volume 1--Principles of Neuropsychopharmacology--contains 9 chapters and provides a tour of the multiple disciplines that undergird the chapters to come, with topics extending from the principles of molecular biology and genomics to the rudiments of neuroimaging and personalized medicine in psychiatry. The second section--Classes of Psychiatric Treatments--contains 38 chapters and provides a comprehensive examination of the medication classes used in psychopharmacological treatment as well as the available neuromodulation therapies. For each drug within a class, data are reviewed on history and discovery, preclinical and clinical pharmacology, pharmacokinetic parameters, mechanism of action, indications and efficacy, side effects and toxicology, and drug-drug interactions. Similar data are provided for brain stimulation modalities. A detailed Index closes this volume.

Volume 2 of the *Textbook* contains the third and final section--Psychopharmacological Treatment--and consists of 20 chapters focused on psychopharmacological approaches to treatment of patients with major psychiatric disorders (e.g., mood and anxiety disorders, schizophrenia, substance use disorders) as well as patients in specific populations (e.g., adults with ADHD, pediatric patients). For each specific condition, patient population, or setting, chapters provide guidance on topics such as medication selection, combination and maintenance dosing regimens, side-effect monitoring and management, and optimization of treatment response. Following these chapters is an Appendix of Psychiatric Medications, with key information on each of the agents covered in the *Textbook*, presented in a convenient tabular format. A detailed Index closes this volume.

Noteworthy additions to this *Textbook* include chapters addressing the following topics:

- Potential roles of personalized medicine in psychiatry and of artificial intelligence and machine learning in psychopharmacology
- New medications with novel pharmacological mechanisms, including ketamine and esketamine, the neurosteroid antidepressant brexanolone, and the atypical antipsychotic pimavanserin
- Use of investigational agents, such as psychedelics, in psychiatric treatment
- Treatment of alcohol use disorder, PTSD, OCD, and autism spectrum disorder
- Treatment of ADHD in adults
- Treatment of women in all life phases, including during pregnancy and the postpartum period
- Treatment of individuals with intellectual developmental disorder

With a level of detail not found in any other source, our new edition of *The American Psychiatric Association Publishing Textbook of Psychopharmacology* illuminates the path to effective evidence-based practice of psychopharmacology for novice and seasoned clinicians alike. We hope you will share our great enthusiasm for this Sixth Edition of the *Textbook of Psychopharmacology*.

This *Textbook* would not have been possible without the superb work of our managing editors, Adrienne Bronfeld and Kelly Puzdrak, who coordinated the efforts and time lines of the chapter authors. In addition, we wish to thank John McDuffie, who recently retired from his position as Publisher of American Psychiatric Association Publishing, for his support of this and previous editions. Greg Kuny, Managing Editor for Books, who also retired recently, has been steadfast in his editing and handling of the details of manuscript preparation. We are fortunate that his successor, Jennifer Gilbreath, has taken on this role for the Sixth Edition *Textbook*. We also are appreciative of the efforts of Rebecca Richters (Senior Editor, Books), Tammy Cordova (Senior Graphic Design Manager), Judy Castagna (Assistant Director of Production Services), and Erika Parker (Acquisitions Editor), Annie Birge (Acquisitions Coordinator), Christie Couture (Associate Director, Marketing), and Margaret May (Marketing Associate) on this and other textbooks we have edited. Robert B. MacArthur, Pharm.D., has provided superb editorial assistance in ensuring accurate information regarding formulations and dosages of all available medications. Basic Principles of Molecular Biology and Genomics

In the early years of the twenty-first century, corporate and government-funded efforts succeeded in the initial sequencing of the human genome (Lander *et al.* 2001; Venter *et al.* 2001). This landmark achievement facilitated a "genetic revolution" that has seen rapid advances in the biomedical sciences. In only two decades, genome-wide profiling technologies have provided unprecedented insights into basic biological mechanisms and disease states. Much new knowledge is generated continuously by in-depth studies of the human and a plethora of other genomes ranging from worms to primates. Notably, because classic protein-coding genes account for only 1%-2% of the human genome, many investigators have devoted their attention to the remaining "dark matter," with surprising new findings pertaining to regulation of gene expression.

Curation of genome-and transcriptome-wide profiling data has produced several publicly available biological repositories such as The Encyclopedia of DNA elements (ENCODE), Entrez Gene, Ensembl, GENCODE, and FANTOM. While fewer protein-coding genes than initially predicted have been identified, genome annotation efforts have uncovered a vast quantity of non-protein-coding genes that contribute to complex gene regulation networks. Further complexity derives from the observation that genes can have transient roles during embryogenesis or functionalities that are specific to a particular tissue or cell type. Despite rapid progress, further elucidation of

gene function and regulation in the developing and adult human brain is necessary to decipher the etiology of psychiatric conditions.

Early studies provided a rudimentary understanding of psychiatric genomics using chromosomal linkage to map putative disease risk genes. High-resolution, single-nucleotide sequencing technologies, in combination with sophisticated bioinformatic tools, have permitted the identification of specific gene variations associated with psychiatric diseases. A growing catalog of genomic aberrations, including insertions, deletions (indels), copy number variations (CNVs), and single nucleotide polymorphisms (SNPs), has shed light on disease processes. These rapid advances in genomics are contemporaneous with the advent of myriad cellular and molecular biology tools, including cellular reprogramming, epigenetic profiling, RNA inhibition, gene transfer, genome editing, chemogenetics, and optogenetics, to name a few. With this tremendous suite of capabilities, researchers are making rapid discoveries that are increasing our collective understanding of biochemical defects and guiding possible new approaches toward ameliorating those defects.

In this chapter, we present information about genetics, genomics, and the genome, as well as providing an overview of modern molecular biology and the investigative methods used in that field. We also discuss pathophysiology, as related to neuropsychiatry and molecular strategy, and introduce findings from studies on the cell biology of the neuron that help us to understand both psychopharmacology and the biology of the brain and mind. Remarkable progress that has transpired since the publication of the previous edition of this book includes an increased appreciation of epigenetic mechanisms in psychiatric disease, broad implementation of genome editing technologies, and increasingly sophisticated tools to control neural activity. FDA approval has now been granted for several viral vector and antisense oligonucleotide therapies for neurological conditions, providing proof of concept for psychiatric disorders. We discuss some of these advances in this chapter, but we caution readers that keeping pace with rapid developments requires continuous observation of relevant literature.

Cell Biology of Neurons and Glia

Neurons are specialized cells that function to transmit signals to other neurons, muscles, and secretory cells. Neurons contain four basic domains (Figure 1-1) that serve to receive signals, process and integrate signals, conduct impulses, and transmit signals.

The nucleus resides in the cell body (the signal processing domain) and contains DNA encoding genes that are expressed by neurons. Activation of a given protein-coding gene results in the generation of a messenger RNA (mRNA) that is subsequently translated into a protein (see below). Although these processes are common to all cells, neural cells are unique in some aspects of molecular signaling. Notably, the variety of genes expressed is far greater in the brain than in any other organ or tissue. It has been estimated that in aggregate, the brain expresses up to 10 times the number of genes expressed in any other tissue. This suggests an extraordinary heterogeneity of gene expression among neurons and glia that allows for a rich regulation when they assemble into the elaborate network of the human brain. Furthermore, neurons are highly specialized, metabolically active cells with robust transcriptional

outputs that are dynamically regulated in response to complex homeostatic fluctuations including neuronal activity.

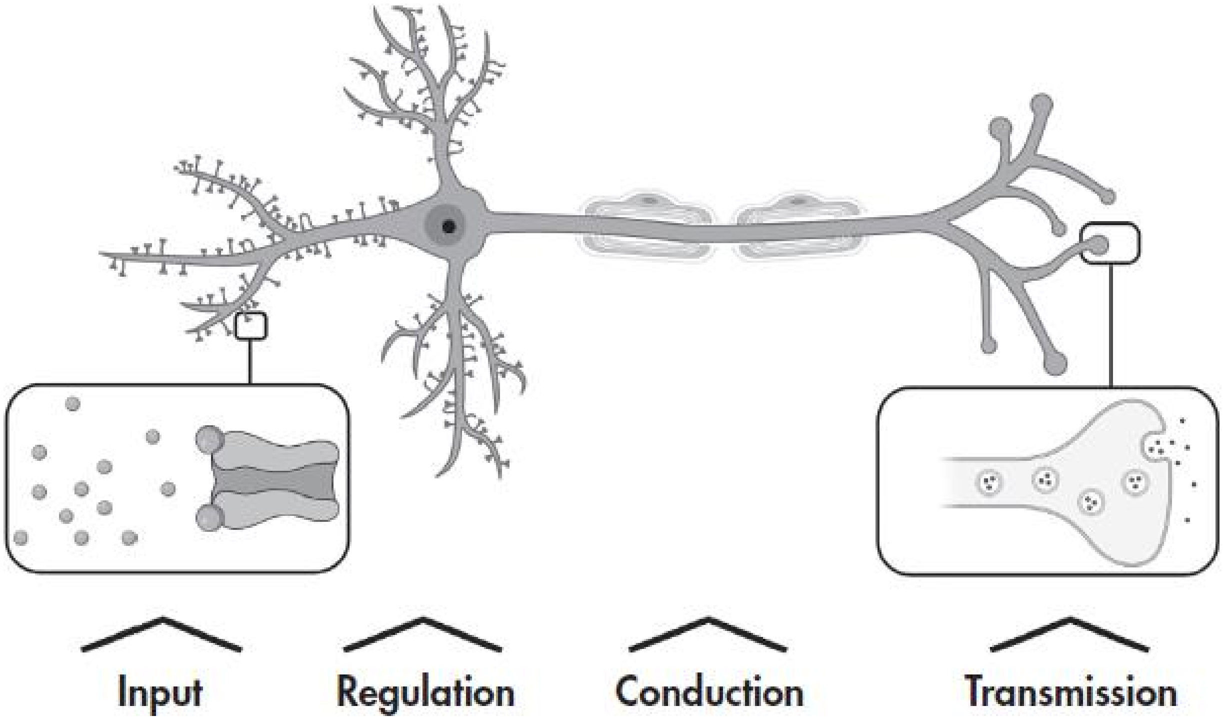

FIGURE 1-1. Diagram of a typical neuron.

As described in the text, this neuron is divided into zones for reception of signals (input = dendrites), integration of signals (regulation = nucleus and soma), conduction of signals (axon), and transmission of signals (axon terminal).

mRNA molecules exported from the nucleus are translated into proteins by ribosomes in the endoplasmic reticulum. Most of the protein production occurs in the cell body, although some mRNA reside at dendrites and are translated locally in response to synaptic activity (Steward and Wallace 1995). Proteins destined for axon termini must be transported from the cell body, a distance that can be as great as 1 meter. These proteins are often packaged in vesicles, and specialized "motor" molecules transport packaged proteins down microtubule "tracks" at the cost of adenosine triphosphate (ATP) hydrolysis (Setou *et al.* 2000).

Essential Principles of Gene Expression

Genes and DNA

The DNA double helix transmits genetic information from generation to generation and is the repository of information required to guide an organism's development and interaction with the environment. The role of DNA in storing and transferring hereditary information depends on the innate properties of its four constituent bases: the two purine bases, adenine (A) and guanine (G), and the two pyrimidine bases, cytosine (C) and thymine (T). Within the DNA double helix, A is complementary to T, and G is complementary to C. Each block of DNA that codes for a single RNA or protein is called a *gene*, and the entire set of genes in a cell, organelle, or virus forms its *genome*. Cells and organelles may contain more than one copy of their genome. When "unraveled," the total DNA of a single human cell is approximately 2 meters in length. This large amount of genetic material is efficiently packed into the cell nucleus, which is also the site of DNA replication and transcription. Only a small percentage of chromosomal DNA in the human genome is composed of protein-coding genes, but modifications such as alternative splicing and RNA editing increase the complexity and number of proteins that are produced from RNA templates.

Importantly, many cellular RNA species (small or long) are noncoding in the sense that they do not have any open reading frame and cannot code for protein synthesis. Every cell contains a dizzying array of RNA species, many of which have been desultorily studied to date. Ribosomal RNA (rRNA), transfer RNA (tRNA), small nuclear RNA (snRNA), microRNA (miRNA), and long noncoding RNA (lncRNA), as well as other RNA species, have independent cellular functions. The most abundant long cellular RNA, mRNA, serves as a template for protein synthesis. RNA, like DNA, is composed of four nucleotide building blocks. However, in RNA, the nucleotide uracil (U) takes the place of thymine (T), and RNA is a flexible single strand that is free to fold into a variety of conformations. Thus, the functional versatility of RNA greatly exceeds that of DNA.

Chromosomal DNA contains both genes and more extensive intergenic regions. Some regions of DNA in genes act as the template for RNA, but some regions are responsible for regulatory functions. The distribution of genes on chromosomes is not uniform; some chromosomal regions, and indeed whole chromosomes, are richly endowed with genes, whereas other regions are more amply supplied with noncoding DNA (although some nongenomic DNA codes for miRNA). Regulation of gene expression conferred by the nucleotide sequence of a DNA molecule is referred to as *cis*-regulation, because the regulatory and transcribed regions occur on the same DNA molecule. *Cis*-Regulatory elements that determine the transcription start site of a gene are called *basal* (or *core*) *promoters*; other *cis*-regulatory elements are responsible for tethering different activators and repressor proteins to DNA. There are specific regions of DNA that bind to regulatory proteins. These regulatory proteins may be encoded at any region in the genome, and because they are not coded by the stretch of DNA to which they bind, they are sometimes called *trans*-acting factors. *Trans*-acting factors that regulate the transcription of DNA are also called *transcription factors*.

DNA Replication

Chromosomal DNA must be replicated to coordinate with cell division. Replication begins at a sequence called the *origin of replication*. It involves the separation of the double-helix DNA strands over a short length and the binding of enzymes, including DNA and RNA polymerases. During DNA replication, each existing strand of DNA serves as a template for the synthesis of a new double helix that contains one old strand and one strand that is newly synthesized but complementary. This process is known as *semiconservative replication*. In the process of cell division, each of the 46 double helices is replicated and folded into chromosomes.

Transcription

Only a fraction of all the genes in a genome are expressed in a given cell or at a given time. These genes undergo the process of *transcription*, in which an RNA molecule complementary to one of the gene's DNA strands is synthesized in a 5' to 3' direction, using nucleotide triphosphates. Transcription can be divided into three discrete steps: initiation, mRNA chain elongation, and chain termination. Transcriptional regulation may occur at any step in the process; however, initiation appears to be the primary control point because, in a sense, it is the rate-limiting step. Localization of the transcription start site and regulation of the rate of transcription are essential to initiation. The *cis*- and *trans*-acting factors described earlier in this section all regulate the initiation of transcription.

Translation

Each mRNA in a cell can code for the primary amino acid sequence of a protein, using a triplet of nucleotides (*codon*) to represent each of the amino acids. Some amino acids are represented by more than one codon, because there are more triplet codons than there are amino acids. The codons in mRNA do not interact directly with the amino acids they specify. The translation of the individual codons of mRNA into protein depends on the presence of another RNA molecule, tRNA, which has a cloverleaf structure. On the top leaf of the tRNA structure, three nucleotides form a complementary codon, an *anticodon*, to each mRNA nucleotide triplet. Thus, each mRNA nucleotide triplet can code for a specific amino acid. Each tRNA carries an amino acid corresponding to its anticodon, and when thus "charged," the complex is termed *aminoacyl-tRNA*. Anticodons of aminoacyl-tRNA bind with mRNA codons in ribosomes. Ribosomes, a complex of rRNA and enzymes needed for translation, provide the structure on which tRNA can bind with the codons of mRNA in sequential order.

Initiation of protein synthesis involves the assembly of the components of the translation system. These components include the two ribosomal subunits, the mRNA to be translated, the aminoacyl-tRNA specified by the first codon in the message, guanosine triphosphate (GTP), and initiation factors that facilitate the assembly of this initiation complex. In eukaryotes, there are at least 12 distinct translation initiation factors (Roll-Mecak *et al.* 2000). After the ribosome recognizes the specific start site on the mRNA sequence, which is always the codon AUG coding for methionine, it slides along the mRNA molecule strand and translates the nucleotide sequence one codon at a time, adding amino acids to the growing end of the polypeptide chain (the elongation process). During elongation, the ribosome moves from the 5' end to the 3' end of the mRNA that is being translated. The binding of GTP to the elongation factor Tu (EFTu) promotes the binding of aminoacyl-tRNA to the ribosome (Wieden *et al.* 2002). When the ribosome finds a stop codon (UAA, UGA, or UAG) in the mRNA, the tRNA and the newly synthesized protein are released from ribosomes with the help of release factors that also bind GTP. The translation process is stopped, and a nascent protein exists.

Regulation of Gene Expression

Chromatin and DNA Methylation

Biophysics and molecular biology have revealed that chromatin consists of a repetitive nucleoprotein complex, the nucleosome. This particle comprises a histone octamer, with two copies of each of the histones H2A, H2B, H3, and H4, wrapped by 147 base pairs of DNA. In the octamer, histones H3 and H4 are assembled in a tetramer, which is flanked by two H2A-H2B dimers. A variable length of DNA completes the second turn around the histone octamer and interacts with a fifth histone, H1. H2A, H2B, H3, and H4 are variously modified at their amino-and carboxyl-terminal tails to influence the dynamics of chromatin structure and function (Ballestar and Esteller 2002; Keshet *et al.* 1986; Kornberg and Lorch 1999; Strahl and Allis 2000). Although chromatin provides structure to chromosomes, it also plays a critical role in transcriptional regulation in eukaryotes because it can repress gene expression by inhibiting the ability of transcription factors to access DNA. In fact, chromatin ensures that genes are inactive until their expression is commanded. In the activation process, cells must attenuate nucleosome-mediated repression of an appropriate subset of genes by means of activator proteins that modify chromatin structure. An activator protein displaces nucleosomes, which permits a complex of proteins (general transcription factors) to bind DNA at a promoter and to recruit RNA polymerase.

Cytosine methylation at cytosine-phosphate-guanine (CpG) dinucleotides is the most common modification of the eukaryotic genome, which is catalyzed by a family of DNA methyltransferases, including Dnmt1, Dnmt3a, and Dnmt3b. CpG islands are CpG-rich regions in the genome, which are often but not always located in the promoter regions of genes and some regulatory elements (Jones 2012). Methylation of cytosines within CpG islands inhibits gene expression either by directly interfering with transcription factor binding to DNA (Ballestar and Esteller 2002) or by recruiting methyl-CpG binding domain proteins, which complex with histone deacetylase to transform chromatin to a repressive state (Ballestar and Esteller 2002; Keshet *et al.* 1986). Dnmt1 expression is remarkably high in the embryonic nervous system, consistent with the proposed role for Dnmt1 in maintaining DNA methylation in dividing neural progenitor cells (Cedar and Bergman 2009).

In addition to alterations in DNA methylation, epigenetic modifications to histone tails are thought to regulate a range of cellular functions, including transcription, replication, chromosome condensation, recombination, DNA repair, and the organization of higher-order chromatin within the nucleus (Strahl and Allis 2000). Acetylation and methylation of lysine at histone tails are the two most common histone modifications (Jenuwein and Allis 2001). Hyperacetylation of nucleosomes is strongly associated with transcription and is considered a hallmark of transcriptional activity, acting to weaken the polar interaction between the negatively charged DNA and the positively charged histone proteins and resulting in a relaxed chromatin state (Dindot *et al.* 2009; Ruthenburg *et al.* 2007). Integral components of the transcriptional machinery include histone acetyltransferase and histone deacetylase enzymes, which regulate, respectively, the addition of acetyl groups to and removal of acetyl groups from histone proteins.

The effects of histone methylation on gene function and chromatin state are mainly dependent on the specific residue that is modified. Generally, in activated gene regions, there is an enrichment of histone methylation at H3K4me, H3K36me, or H3K79me (Guenther *et al.* 2007; Heintzman *et al.* 2007; Steger *et al.* 2008). In contrast, the enrichment of histone methylation at H3K9me, H3K20me, or H4K27me is implicated in gene inactivation or silencing (Kouzarides 1999; Ruthenburg *et al.* 2007). Studies also revealed that the degree of histone methylation plays a role in gene expression activity. The trimethylation at residues of H3K9, H3K2, and H4K20 is associated with transcription repression (Barski *et al.* 2007; Mikkelsen *et al.* 2007; Vakoc *et al.* 2006). However, the mono-methylation at these residues represents the gene activation (Barski *et al.* 2007; Vakoc *et al.* 2006). These DNA modifications form the basis of epigenetics, which has taken on a prominent role in relating experience to psychiatric phenotypes (Klengel and Binder 2015).

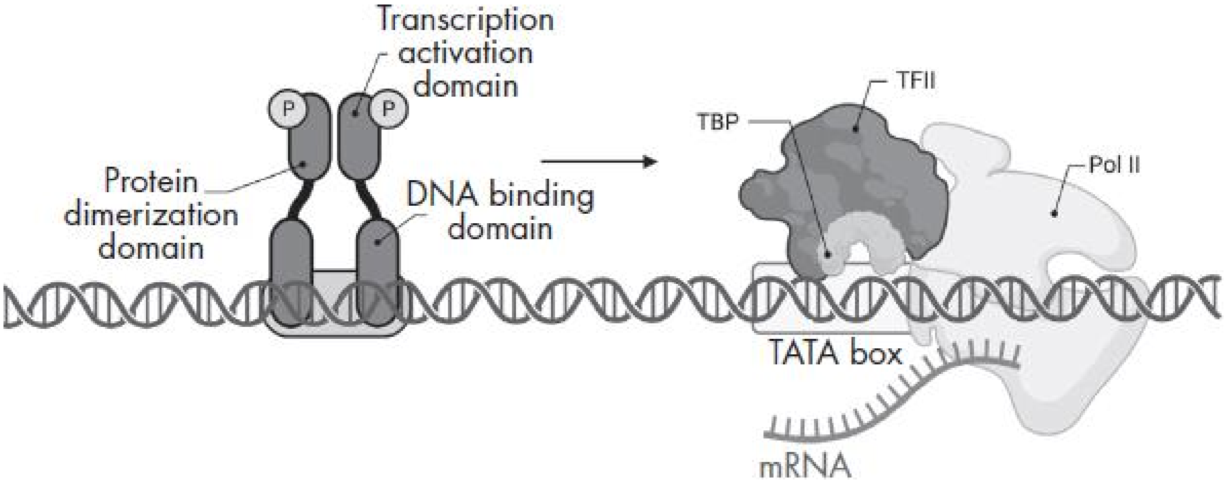

FIGURE 1-2. Transcription factors and RNA polymerase II (Pol II) complex.

Typical transcription factors contain DNA binding domains, dimerization domains, and transcription activation domains. Some transcription factors (e.g., cAMP [cyclic 3'-5'-adenosine monophosphate] response element-binding protein [CREB]) may be modified by phosphorylation. The transcription activation domain interacts with an RNA Pol II complex to induce transcription. TATA box binding protein (TBP) binds to the TATA box element and associates with general transcription factors (TFII). This gene transcription apparatus recruits Pol II to the appropriate gene. TATA box = DNA sequence rich in nucleotides A and T.

RNA Polymerases

There are three distinct classes of RNA polymerase--RNA polymerase I (Pol I), RNA polymerase II (Pol II), and RNA polymerase III (Pol III)--in the nucleus of eukaryotic cells, and they are designed to carry out transcription. RNA Pol I synthesizes large rRNA molecules. RNA Pol II is mainly used to yield mRNA and, subsequently, proteins. RNA Pol III produces small RNA, including rRNA and tRNA molecules. Each class of RNA polymerase recognizes particular types of genes. However, RNA polymerases do not bind to DNA directly. Rather, they are recruited to DNA by other proteins that bind to promoters (Figure 1-2).

mRNA is transcribed from DNA by RNA Pol II, with heterogeneous nuclear RNA (hnRNA) as an intermediate product. The core promoter recognized by Pol II is the TATA box (Hogness box), a sequence rich in nucleotides A and T, which is usually located 25-30 bases upstream of the transcription start site. The TATA box determines the start site of transcription and orients the basal transcription complex that binds to DNA and recruits RNA Pol II to the TATA box; thus, it establishes the 5' to 3' direction in which Pol II synthesizes RNA. The formation of the basal transcription complex is promoted by a TATA box binding protein (TBP) that binds core promoters together with multiple TBP-associated factors and other general transcription factors. *Enhancers* are DNA sequences that increase the rate of initiation of transcription by RNA Pol II through its interaction with transcription factors, which can be located "upstream" or "downstream" of the transcription start site. Enhancer elements are important to cell-specific and stimulus-dependent expression of hnRNA. Some Pol II species, including those for many genes that are expressed in neurons, lack a TATA box and possess instead an *initiator*, a poorly conserved genetic promoter element.

Transcription Factors

Transcription factors act as the key regulators of gene expression. Sequence-specific transcription factors typically contain physically distinct functional domains (see Figure 1-2). Numerous transcription factors have been found. Some of them translocate to the nucleus to bind their *cis*-regulatory elements in response to their activation reaction, such as nuclear factor kB (NF-kB). However, some transcription factors are already bound to their cognate *cis*-regulatory elements in the nucleus under basal conditions and are converted into transcriptional activators by phosphorylation. cAMP (cyclic 3'-5'-adenosine monophosphate) response element-binding protein (CREB), for example, is bound to regions of DNA, called *cAMP response elements* (CREs), before cell stimulation. CREB can promote transcription when it is phosphorylated on a serine residue (ser133), because phosphorylated CREB can interact with a coactivator, CREB-binding protein (CBP), which in turn contacts and activates the basal transcription complex. Of interest, CBP possesses intrinsic histone acetyltransferase activity. The activity of most transcription factors is regulated though second-messenger pathways. CREB can be activated via phosphorylation at ser133 by second messengers such as cAMP, Ca^{++}, and growth factors (Kandel 2012) (Figure 1-3).

CREB is a molecule that is widely implicated in learning and memory in many species. Mice expressing mutant CREB isoforms show impaired memory, but this result is dependent on the genetic background of the mice (Graves *et al.* 2002). CBP is a transcriptional coactivator with CREB. A partial-knockout mouse model, in which CBP activity is lost, exhibits learning deficiencies (Oike *et al.* 1999). Furthermore, Rubinstein-Taybi syndrome (RTS) is an autosomal-dominant dysmorphic syndrome that results in severe impairment of learning and memory. The RTS gene has been mapped to chromosome 16 and identified as CBP. Loss of CBP function is likely one important contributing factor to the learning and memory defects seen in RTS (Murata *et al.* 2001; Oike *et al.* 1999; Petrij *et al.* 1995).

Posttranscriptional Modification of RNA

The mRNA of prokaryotes can be used, without any modification, to direct protein synthesis, but posttranscriptional processing of mRNA is required in eukaryotes. The DNA sequences that code for mRNA (exons) are frequently interrupted by intervening DNA sequences (introns). When a protein-coding gene is first transcribed, the hnRNA contains both exons and introns. Before the transcript exits the nucleus, its introns are removed and its exons are spliced to form mature mRNA (Figure 1-4). The hnRNA that is synthesized by RNA polymerase has a 7-methyl-guanosine "cap" added at the 5' end. The cap appears to facilitate the initiation of translation and to help stabilize the mRNA. In addition, most eukaryotic mRNAs have a chain of 40-200 adenine nucleotides attached to the 3' end. The poly(A) tail is not transcribed from DNA; rather, it is added after transcription by the nuclear enzyme poly(A) polymerase. The poly(A) tail may help stabilize the mRNA and facilitate mRNA exit from the nucleus. After the mRNA enters the cytoplasm, the poly(A) tail is gradually shortened.

RNA Editing

RNA editing has been observed in eukaryotes ranging from protozoa to mammals and is now recognized as a type of RNA process (posttranscriptional modification of RNA) that differs from the well-known processes of RNA splicing, 5' end formation, and 3' endonucleolytic cleavage and polyadenylation (DeCerbo and Carmichael 2005; Kable *et al.* 1997). The conversion of adenosine to inosine was observed first in yeast tRNA (Grosjean *et al.* 1996) but has since been detected in viral RNA transcripts and mammalian cellular RNA (Bass 1997; Simpson and Emeson 1996). The inosine residues generated from adenosines can alter the coding information of the transcripts, because inosine is synonymous for guanosine during transcript translation. For example, upon A-to-I editing, the CAC codon for histamine is transformed to CIC, coding for arginine. RNA editing can have dramatic consequences for the expression of genetic information, and in a number of cases it has been shown to lead to the expression of proteins not only with altered amino acid sequences from those predicted from the DNA sequence but also with altered biological functions (Bass 2002; Burns *et al.* 1997).

The enzymes for RNA editing are referred to as *adenosine deaminases that act on RNA* (ADARs). ADARs target double-stranded RNA (dsRNA) and convert adenosines to inosines by catalyzing a hydrolytic deamination at the adenine base (Bass 2002). Mammals have several ADARs, of which two, ADAR1 and ADAR2, are expressed in most tissues of the body (Seeburg and Hartner 2003). RNA editing may also catalyze the conversion of a small number of adenosines in a transcript to inosines (Stuart and Panigrahi 2002). On the other hand, RNA editing can convert numerous adenosines to inosines in RNA. This type of editing is thought to be the result of aberrant production of dsRNA (DeCerbo and Carmichael 2005) and has been suggested to lead to RNA degradation (Scadden and Smith 2001), nuclear retention (Zhang and Carmichael 2001), or even gene silencing (Wang *et al.* 2005).

The serotonin 5-HT$_{2C}$ receptor is a G protein-coupled receptor that has variants generated by A-to-I editing (Burns *et al.* 1997). 5-HT$_{2C}$ receptor transcripts can be edited at up to five sites, potentially generating 24 different receptor versions and hence a diverse receptor population. The RNA-edited 5-HT$_{2C}$ receptor affects ligand affinity and the efficacy of G protein coupling (Berg *et al.* 2001; Wang *et al.* 2000; Yang *et al.* 2004). The unedited form of the 5-HT$_{2C}$ receptor has the highest affinity to serotonin and exhibits constitutive activity independent of serotonin or serotonergic agonists. When RNA is edited, the basal activity of the 5-HT$_{2C}$ receptor is suppressed and agonist potency and efficacy are modified.

Noncoding RNAs

About 2% of the human genome is transcribed into mature protein-coding RNAs, whereas the large majority, 70%-90%, is transcribed into non-protein-coding RNAs (ncRNAs). Classes of noncoding transcripts can be divided between housekeeping ncRNAs and regulatory ncRNAs.

Housekeeping ncRNAs include rRNA, tRNA, snRNA, and small nucleolar RNAs and are usually expressed constitutively. Regulatory ncRNAs can be classified into miRNAs, Piwi-interacting RNAs (piRNAs), small interfering RNAs (siRNAs), promoter and enhancer RNAs, and lncRNAs (Kaikkonen *et al.* 2011; Ponting *et al.* 2009). The majority of the non-protein-coding transcripts belong to the group of lncRNAs, which are arbitrarily considered as greater than 200 nucleotides in length (Ponting *et al.* 2009). However, many of these lncRNAs can also act as primary transcripts for the production of short RNAs, making the categorization of this group of ncRNAs ambiguous (Kaikkonen *et al.* 2011). The best-known ncRNAs are endogenous siRNAs. siRNAs, together with miRNAs and piRNAs, play an instrumental regulatory and defensive role in organisms. These three classes of small RNAs show overlap with regard to their structure, synthesis, and biological role. Endogenous siRNAs are involved in gene regulation and transposon silencing, although the latter mechanism is still not understood.

Modification of the Nascent Polypeptide Chain

Posttranslational modifications occur after translation is initiated. These modifications may include removal of part of the translated sequence or the covalent addition of one or more chemical groups that are required for protein activity. Some of these modifications, such as glycosylation or prenylation, represent an obligatory step in the synthesis of the "finished" protein product. In addition, many proteins may be activated or inactivated through covalent attachment of a variety of chemical groups. Phosphorylation, glycosylation, hydroxylation, and prenylation are common types of covalent alterations in posttranslational modifications. A number of different enzymes coordinate these processes, and they represent a major portion of the events of cellular signaling.

Experimental Approaches to Determining and Manipulating Gene Expression

Changes in gene expression within the CNS have profound effects for all other aspects of the organism. Changes in gene expression are causally associated not only with the development of the CNS but also with the complex phenomena of brain function, such as memory formation, learning, cognition, and affective state. Changes in gene expression may underlie the pathogenesis of many sporadic or inherited CNS-related disorders, such as Alzheimer's disease, Huntington's disease, depression, and schizophrenia. Thus, insight into and characterization of gene expression profiles are necessary steps for understanding how the brain functions at the molecular level and how malfunction will result in disease. Molecular biological and genomic technologies such as gene mapping and cloning, DNA libraries, gene transfection and expression, and gene knockout and gene targeting have provided numerous benefits to neuropsychopharmacology. Genomic methods applied to pedigree and population samples of patients with psychiatric disorders may soon make it possible to identify genes contributing to the etiology and pathogenesis of these diseases and to provide a potential basis for new therapies.

Cloning of DNA

The cloning of DNA confers the ability to replicate and amplify individual pieces of genes. Cloning can be performed with genomic DNA or complementary DNA (cDNA) that is synthesized artificially from mRNA in vitro with the aid of *reverse transcriptase*. Cloned genomic DNA may contain any stretch of DNA, either intron or exon, whereas cloned cDNA consists only of exons. For cloning (this process is outlined in Figure 1-5), the desired pieces of DNA (often called "inserts") are connected with the DNA of genetically engineered vectors or plasmids and then introduced into hosts such as bacteria or mammalian cells. A DNA library is a collection of cloned restriction fragments of the DNA of an organism that consists of random pieces of genomic DNA (i.e., genomic library) or cDNA (i.e., cDNA library). Complete cDNA libraries contain all of the mRNA molecules expressed in a certain tissue. Sometimes cDNA libraries can be from a specific tissue in a distinct circumstance. For example, a cDNA library could be made from cerebral cortex in rats with transient forebrain ischemia (Abe *et al.* 1993).

The cloning of disease-related genes is an important step toward insight into the pathogenesis of diseases and development of new drugs against these diseases. If a protein is suspected of involvement in pathogenesis, a nucleic acid sequence can be deduced from the partial amino acid sequence. cDNA libraries are screened with the partial sequence in order to extract a complete clone of interest. The isolated cDNA molecules are transferred to bacteria, which amplify the cloned cDNA. Bacteria expressing these cDNA molecules will often make the protein of interest, which can be detected with antibody. A variation on the above technique uses antibodies against the purified proteins to screen a DNA library transfected into bacteriophages. The bacteriophages containing the "right" cDNA can be retrieved, and the sequence of cDNA can be analyzed.

Positional Cloning

Disease genes can sometimes be isolated with the aid of *positional cloning*, a process also known as *reverse genetics* (Collins 1995). Positional cloning is the process used to identify a disease gene based only on knowledge of its chromosomal location, without any knowledge of the gene's biological function. Positional cloning requires a genetic map of unique DNA segments or genes (genetic markers), with known chromosomal locations, that exist in several alternative forms (alleles). These allelic variations (polymorphisms) allow comparisons of the wild type as the "diseased" genotype. Linkage analysis is a method of localizing one or more genes influencing a trait to specific chromosomal regions. Genetic linkage analysis is performed by examining the cosegregation of the phenotype of interest with genetic markers. Relatives who are phenotypically alike will share common alleles at markers surrounding the genes influencing the phenotype, whereas relatives who are phenotypically dissimilar will not share these alleles. To carry out linkage analyses, investigators need, minimally, a set of families in which phenotypic individuals have known relationships to one another and the genotypes of these individuals, including one or more genetic markers.

Once the chromosomal location of the disease gene has been ascertained, the area of chromosomal DNA can be cloned. Until recently, the process of positional cloning involved laborious efforts to build a physical map and to sequence the region. (The sequencing of the human genome has obviated this step). Physical maps can be produced by isolating and linking together yeast and/or bacterial artificial chromosomes containing segments of human DNA from the region. These fragments are then sequenced and ordered, and from these data, the genomic DNA sequence for the region of the candidate gene is determined.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a rapid procedure for in vitro enzymatic amplification of specific segments of DNA. Amplification of the genes of interest involves selecting and synthesizing "primers"--stretches of DNA that span the region of interest to be "filled in"--and heating DNA to "melt" into single-stranded DNA, allowing polymerase and primers to bind. The polymerase then reads the "blank" stretch of DNA between the primers and synthesizes DNA corresponding to the region of interest. PCR is usually performed in thermal cyclers that heat the DNA at regular intervals and allow "cycles" of PCR to amplify the genes repetitively. To avoid continual addition of polymerase, laboratories use DNA polymerase from bacteria that inhabit hot springs or hot ocean vents. These polymerases are resistant to denaturing by heat and can therefore support several cycles of PCR.

A variation on PCR is *reverse transcriptase PCR* (RT-PCR), in which the RNA is the template. Retroviral reverse transcriptase is employed to synthesize cDNA from RNA. Enzymatic amplification of this cDNA is then accomplished using PCR. Traditional PCR is an end-point method, whereas real-time PCR is more quantitative because of detection chemistries that report the presence of PCR products after each round of amplification. PCR chemistries consist of fluorescent probes including DNA-binding dyes (ethidium bromide or SYBR Green I), hydrolysis probes (5'-nuclease probes), and hybridization probes (Valasek and Repa 2005). Each type of probe has its own unique characteristics, but the strategy for each is to link a change in fluorescence to amplification of DNA (Kubista *et al.* 2006). The instrumentation to detect the production of PCR must be able to input energy for excitation of fluorescent chemistries at the desired wavelength and simultaneously detect a particular emission wavelength. Many instrument platforms are available for real-time PCR.

Next-Generation Sequencing

The quantification of RNA using real-time RT-PCR is a routine method of assessing gene expression. However, important limitations are the small number of genes that can be assayed in one experiment and potential artifacts due to PCR amplification. Alternative, hybridization-based technologies such as microarray and NanoString use fluorescent probes that are complementary to known target sequences and attached to a solid substrate. After hybridization with samples, microscopic imaging of the substrate is then used to compute transcription rates for many genes simultaneously. Although there are instances where these technologies are advantageous, they have largely been replaced by the preeminent technology for profiling global RNA expression, massively parallel "next generation" RNA sequencing.

Reagents and instruments for RNA sequencing sold by Illumina, Inc., have been broadly adopted across academic, clinical research, biotechnology, and pharmaceutical sectors. Illumina sequencing technology involves four steps: sample preparation, cluster generation, sequencing by synthesis, and data analysis. Sample preparation involves ligation of adapter sequences to the 5' and 3' ends of fragmented template DNA or cDNA reverse transcribed from RNA. Template DNA is then amplified by PCR using primers complementary to the adapter sequences. During this process, additional sequences are added to ends of DNA amplicons to allow for sequence indexing and attachment of fragments to a solid substrate called a flow cell. The flow cell is a glass slide with lanes that contain a "lawn" of oligonucleotides complementary to adapter sequences of DNA templates. Adapter-ligated DNA is hybridized to oligonucleotides on the flow cell and clonally amplified to produce millions of "clusters" that represent the template sequences in discrete physical space on the flow cell. Detection of cluster sequences relies on their synthesis using fluorescently labeled nucleotides, each having a unique emission wavelength. As nucleotides are incorporated into the new DNA strand according to the sequence of template DNA, the sequence is inferred from the emission of light from newly incorporated nucleotides. The emission wavelength and intensity are measured in a massively parallel process for hundreds of millions of clusters on the flow cell. Billions of sequencing "reads" of 100 to 150 base pairs are produced in single or paired-end workflows, representing all the template fragments from a given sample. Sequencing reads are bioinformatically assembled into a contiguous sequence and aligned to the reference genome. Although the Illumina platform has dominated the industry, alternative technologies such as Ion Torrent and Nanopore sequencing are among their competitors.

Because of the large size of mammalian genomes, achieving sufficient read depth across the entire genome can be cost prohibitive. Therefore, as an alternative to whole-genome sequencing, whole-exome sequencing may be used, wherein only the protein-coding regions of the genome are sequenced. Once data are generated and analyzed, associations between phenotypes and genetic variations within a population may be assessed using various study designs, including genome-wide association studies (GWAS). Differential gene expression can be assessed by RNA sequencing, wherein the number of reads that are mapped to a given gene (read count) is used to infer gene expression levels.

A major limitation of most gene expression studies is the use of bulk RNA preparations from complex tissues containing multiple cell types. In response to this, single-cell RNA sequencing (scRNA-seq) is rapidly gaining popularity because of the ability to obtain high-resolution, cell-type-specific gene expression data from heterogeneous tissues like the CNS. However, the complex architecture of the adult brain and elaborate neuronal morphologies make it resistant to dissociation into intact single-cell preparations suitable for scRNA-seq. Therefore, cellular nuclei isolated from brain tissues are typically used for scRNA-seq studies. Notably, cellular nuclei are structurally resilient, enabling single-nuclei RNA sequencing to be carried out on frozen brain tissues. Assessing transcriptional landscapes at single-cell resolution is particularly important for the neurosciences due to the presence of non-neuronal CNS cells such as glia, epithelial cells of the vasculature, and blood that far outnumber neurons.

Gene Delivery Into Mammalian Cells

The introduction of recombinant DNA (including desired genes) into cells is an important strategy for understanding certain gene functions in neurons or glia. Gene function studies have benefited diagnosis and therapy for a variety of disorders that affect the CNS. The delivery of desired genes into cells or brain regions provides the technological base for insight into molecular mechanisms of brain function and, ultimately, for gene therapy in the CNS.

Vectors and Delivery

For gene transfer, it is necessary to incorporate the desired cDNA into vectors, such as engineered expression plasmids or replication-deficient viruses. Vectors used for transfection generally possess two essentially independent functions: 1) carrying genes to the target cell and 2) expressing the genes properly in the target cell. In one form of transfection, *stable transfection*, cells expressing the gene of interest can be actively selected by a marker (e.g., neomycin resistance genes, *Neo*), and the cDNA or other type of foreign DNA is eventually integrated into the genome of host cells, conferring continuous expression in daughter cells. In *transient transfection*, however, foreign DNA is not integrated into the genome of cells, and thus genes of interest are only expressed for a few days.

The main barrier to the delivery of DNA into cells is getting the foreign DNA through the cellular membrane. Various chemical and physical methods have been developed to convey the foreign DNA, such as calcium phosphate coprecipitation of DNA, liposome fusion, electroporation, microinjection, ballistic injection, and viral infection. At present, methods dependent on incorporation of DNA into cationic liposomes are used most widely (e.g., lipofectin). These methods of transfection are accessible to both cell lines and cultured primary neuronal cells. Cells for hosting the foreign DNA can be either established cell lines or primary cultured neuronal cells. The desired cDNA delivered into cells may be native genes, fragments of the genes, mutant genes, or chimeric genes.

Viral Vectors

Several viral vectors with low toxicity, high transduction efficiency, and persistent expression have extended the methodology of delivery of genes to mammalian cells. These viruses include DNA viruses, such as adenoviruses and adeno-associated viruses (AAVs), herpes simplex viruses, and RNA retroviruses. As a result of advances in genetic manipulation, adenoviruses and AAVs are now more widely applied to gene transfer. The advantages of the adenoviruses are 1) the ability to carry large sequences of foreign DNA, 2) efficient transduction of a broad range of cell types 3) an almost 100% expression of the foreign genes in cells, and 4) an extremely low rate of integration into host genomes. AAV viral vectors share these attributes but have a limited payload capacity.

Human adenovirus is a large DNA virus (containing about 36 kilobase [kb] pairs) composed of early viral genes (from *E1* to *E4*) and later genes (from *L1* to *L5*). Wild-type adenovirus cannot be applied to gene transfer because it causes a lytic infection. Thus, recombinant adenoviruses with defects of some essential viral genes are used for gene delivery. These adenoviral expression systems are safe, have the capacity for large DNA inserts, and allow for relatively simple adenoviral production (Harding *et al.* 1997; He *et al.* 1998).

Meanwhile, AAV vectors have emerged as a dominant vector platform in biomedical research and clinical settings (Hastie and Samulski 2015; Wu *et al.* 2006; Xie *et al.* 2002). Clinical trials evaluating AAV vectors have shown they are well tolerated (Keeler and Flotte 2019), and effective AAV vectors have been approved for the treatment of lipoprotein lipase deficiency (Buning 2013; Yla-Herttuala 2012), Leber congenital amaurosis (Luxturna) (Dunbar *et al.* 2018), and spinal muscular atrophy (Zolgensma) (Keeler and Flotte 2019). Projections from the FDA suggest that by 2025, approximately 10 new approvals for viral vector-based drugs will be awarded annually.

All known AAV serotypes require co-infection with a helper virus to manifest productive infection. Thus, AAV is classified as a *dependovirus* that is naturally nonpathogenic. The AAV genome consists of a 4.7-kb single-stranded DNA with inverted terminal repeats (ITRs) packaged into a small non-enveloped icosahedral capsid (Wu *et al.* 2006). The short (145-base) ITRs are sufficient for vector propagation when viral *Rep* (Replication) and *Cap* (Capsid) genes are provided in trans. Therefore, with the exception of ITRs, the entire AAV genome can be replaced to accommodate a desired genetic payload.

Lentivirus belongs to the *Retroviridae* family that also includes HIV. The 8-kb lentiviral genome is a single-stranded RNA encoding several viral genes flanked by long terminal repeats. The ability of lentiviral vectors to efficiently integrate into the host genome of nonreplicating cells (including neurons) and confer stable transgene expression makes them an attractive option for gene transfer in the neurosciences. To minimize the potential for creating replication-competent vectors during production, third-generation lentiviral vector systems distribute viral genes among four different plasmids. While this practice has vastly increased the safety of lentiviral vectors, their random integration into the host genome can result in insertional mutagenesis.

Given the innate capacity of viral vectors to attach and transmit genetic material across the cell membrane, gene transfer can be achieved simply by physical interactions between viral vectors and cells. To maximize the efficiency of transduction, viral titer, the time of exposure to virus, and the multiplicity of infection should be optimized for each vector system and cell or tissue type. For in vivo studies, intracranial infusions of viral vectors into discrete brain regions result in local transgene expression, although vector titer, infusion volume, and vector selection are among critical parameters that affect dissemination, duration, cell-type specificity, and levels of transgene expression. Global transduction of the rodent brain requires infusion of viral vectors at an early postnatal time point.

Several general strategies can be employed to assess proper expression of transgenes following viral vector transduction (Chalfie *et al.* 1994; Czysz *et al.* 2015; Kohara *et al.* 2001; Yu and Rasenick 2002):

1. The measurement of functional changes elicited by gene expression in targeted cells. If an enzyme is expressed, this would involve measuring the activity of that enzyme.
2. The detection of the proteins encoded by transgenes via techniques relying on antibodies, such as western blot, immunoprecipitation, and immunocytochemistry. Expression of the desired genes tagged with some epitopes, such as hemagglutinin (HA), glutathione S-transferase

(GST), and polyhistidine tag (His-tag), can also be determined using antibodies directed against these epitopes.

3. The use of fluorescent proteins such as the green fluorescent protein as an indicator.

The improved safety and efficiency of modern viral vector systems makes them an increasingly attractive therapeutic avenue for neurological and psychiatric conditions, particularly for disorders with a known genetic etiology. Combined with emerging gene editing tools, viral vectors are likely to become an important addition to the therapeutic repertoire.

Inhibition of Cellular Gene Expression

RNA Interference

RNA interference (RNAi) is believed to be a biologically conserved function in a wide range of eukaryotic species. It may play a role in protection against dsRNA viruses (Sijen *et al.* 2001) and genome-invading transposable elements (Provost *et al.* 2002; Volpe *et al.* 2002). Triggered by dsRNA, RNAi identifies and destroys the mRNA that shares homology with the dsRNA. This natural defense mechanism can be exploited to suppress the expression of any particular gene by introducing dsRNA whose antisense strand sequence matches the mRNA sequence. The first described RNAi was in the nematode *Caenorhabditis elegans* as sequence-specific gene silencing in response to dsRNA (Fire *et al.* 1998).

FIGURE 1-6. Schematic of the mechanism of RNA interference (RNAi) posttranscriptional knockdown of a gene product.

The procedure starts with the introduction (transfection, electroporation, or injection) of double-stranded RNA (dsRNA) or small interfering RNA (siRNA) into cells, or expression of small hairpin RNA (shRNA) in cells with vectors encoding shRNAs. The cellular ribonuclease (RNase) Dicer recognizes the long dsRNA molecules and shRNA. Subsequently, the dsRNA is cleaved, resulting in 21-nucleotide RNA duplexes, the siRNAs. These siRNA molecules are then incorporated into the RNA-induced silencing complex (RISC), where they are unwound by an adenosine triphosphate (ATP)-dependent process, transforming the complex into an active state. Activated RISC uses one strand of the RNA as a bait to bind homologous RNA molecules. The target RNA is cleaved and degraded, resulting in gene silencing. mRNA = messenger RNA; Pol III = RNA polymerase III.

In the initiation step, Dicer, an enzyme of the RNase III family, initiates ATP-dependent fragmentation of long dsRNA into 21-to 25-nucleotide double-stranded fragments, termed *small interfering RNAs*. These siRNAs re specifically characterized by overhanging 3' ends of two nucleotides and phosphorylated 5' ends. The siRNA duplexes bind with Dicer, which facilitates the formation of an siRNA/multiprotein complex called *RISC loading complex* (RLC). The siRNA duplex in RLC then unwinds (which requires the protein Ago2) to form an active *RNA-induced silencing complex* (RISC) that contains a single-stranded RNA (called the *guide strand*). The RISC recognizes the target RNA through Watson-Crick base pairing with the guide strand and cleaves the target RNA. Finally, the RISC releases its cleaved product and goes on to catalyze a new cycle of target recognition and cleavage (Figure 1-6) (Tomari and Zamore 2005; Xia *et al.* 2005).

miRNAs are formed in a similar manner, from longer RNA precursors, and are processed in the cytoplasm by Dicer before becoming part of a RISC. However, siRNAs are the products of exogenous dsRNAs that are taken up by cells or that enter via vectors such as viruses. siRNAs bind to mRNA in the case of complete complementarity. miRNAs are products of endogenous ncRNA encoded from genes of the genome. They do not require full complementarity to bind with target mRNA (e.g., one type of miRNA may regulate many genes, and one gene may be regulated by several miRNAs) (Carthew and Sontheimer 2009).

Antisense Oligonucleotide or RNAi Knockdown of Gene Expression

Knockdown of gene expression is accomplished by designing antisense oligonucleotide (ASO) or siRNA sequences that target the coding and noncoding regions of the specified mRNAs with perfect complementarity. In mammalian cells, administration of siRNAs is effective in short-term investigations. Introduction of ASO or siRNA into cells is accomplished by transfection or electroporation of either the specific siRNA itself or small hairpin RNA (shRNA), in which the hair loop is rapidly cleaved to produce siRNA. Most of the proposed applications of RNAi incorporate 21-nucleotide siRNA duplexes that have 2-nucleotide 3' overhangs, which allow large-scale and uniform production of siRNA molecules that can be chemically stabilized. In some siRNA-target combinations, the use of longer dsRNAs can increase the potency of RNAi (Kim *et al.* 2005; Siolas *et al.* 2005).

For stable longer-term suppression, a gene construct coding for the shRNA with a Pol III or a Pol II promoter can be applied (Brummelkamp *et al.* 2002; Shi *et al.* 2006). RNA Pol II and III promoters are used to drive expression of shRNA constructs (Amarzguioui *et al.* 2005), depending on the type of expression required. Pol III promoters drive high levels of constitutive shRNA expression, and their transcription initiation points and termination signals are well defined. Pol II promoter-driven shRNAs can be expressed tissue-specifically (Zeng *et al.* 2002). Expressed shRNAs are incorporated into a RISC, leading to a more potent inhibition of target gene expression. Generally, viral vectors such as adenovirus, lentivirus, and AAC can carry the gene construct into cells to achieve adequate and prolonged expression for knockdown (Kim and Rossi 2007).

Oligonucleotide Applications

ASOs and RNAi constitute a straightforward method for inducing sequence-specific silencing of one or more genes of interest with the introduction of ASO, siRNAs, or shRNAs. These have been powerful tools for investigating gene function in laboratory settings. Meanwhile, these same types of oligonucleotides can be used in vivo and as therapeutic agents. In the 30 years that have passed since the first studies of ASOs applied directly to the living brain (Wahlestedt *et al.* 1993a, 1993b), clinical success has been achieved in human patients, notably with the recent FDA approval of Spinraza for spinal muscular atrophy (Finkel *et al.* 2017).

Studies using RNAi have been performed in neuronal cells to examine the functional roles of individual genes in developing growth cones and neurite outgrowth (Eriksson *et al.* 2007; Hengst *et al.* 2006; Liu *et al.* 2007; Schmitz *et al.* 2007; Yanaka *et al.* 2007), ion channels (Geng *et al.* 2004;

Lauver *et al.* 2006; Tahiliani *et al.* 2007), apoptosis (Yano *et al.* 2007; Zhang *et al.* 2007), and a variety of signaling pathways (Meuer *et al.* 2007; Sanada and Tsai 2005; Shi *et al.* 2006; Yamada *et al.* 2005). Furthermore, like ASOs, RNAi can be used for the knockdown of gene expression in animals. It appears to apply in virtually all mammalian species, as exemplified by its capability for silencing genes in mice, rats, and goats (Peng *et al.* 2006; Zhou *et al.* 2007). Inducible RNAi based on the Cre-loxP system has also been developed in transgenic mice, enabling the investigator to control gene silencing both spatially and temporally (Chang *et al.* 2004; Coumoul *et al.* 2005; Peng *et al.* 2006; Xia *et al.* 2006; Zhou *et al.* 2007).

To conclude, the success of ASO and RNAi knockdown of specific genes is increasingly translated for therapeutic gene disruption in patients with genetic diseases. ASOs and RNAi have long been a frequently used tool in a wide range of biomedical research.

Chromatin Profiling Techniques

The purpose of *chromatin immunoprecipitation* (ChIP) is to identify genomic sequence(s) associated with a protein of interest (Solomon *et al.* 1988). ChIP has become the technique of choice to determine the genomic enrichment profiles of transcription factors, posttranslationally modified histones, histone variants, or chromatin-modifying enzymes. The method comprises three basic steps: 1) covalent crosslinks between proteins and DNA are formed, typically by treating cells with formaldehyde or another chemical reagent; 2) an antibody specific to the protein of interest is used to coimmunoprecipitate the protein-bound DNA fragments that were covalently crosslinked; and 3) the immunoprecipitated protein-DNA links are reversed. DNA sequences associated with the precipitated protein can be identified in various ways, including dot or slot blot, PCR, quantitative PCR, labeling and hybridization to genome-wide or tiling DNA microarrays (ChIP-chip technique) (Lee *et al.* 2006), and sequencing technology (Gogol-Doring and Chen 2012).

Optimized workflows for ChIP followed by DNA sequencing (ChIP-seq) have been commercialized and used extensively in epigenetic profiling studies, but some important limitations persist. For example, ChIP-seq is laborious, requires substantial optimization, is prone to artifact, and requires large amounts of starting material--a major limitation for analyzing small amounts of tissue or low-abundance cell types. An alternative technique gaining popularity is the *cleavage under targets and release using nuclease* (CUT&RUN), a novel chromatin mapping strategy that is less labor-intensive, provides lower background, and requires less starting material than ChIP-seq (Skene *et al.* 2018). CUT&RUN builds on Chromatin ImmunoCleavage (ChIC), wherein a fusion of protein A to Micrococcal Nuclease (pA-MNase) selectively cleaves antibody-bound chromatin in situ (Schmid *et al.* 2004). In CUT&RUN, cells or nuclei are immobilized to a solid support, with pA-MNase-cleaved DNA fragments isolated from solution. The workflow is compatible with next-generation sequencing to generate high-resolution genome-wide profiles of histone posttranslational modifications, going from cells to analyzed data in less than 1 week.

Another important technique for assessing chromatin accessibility on a genome-wide scale is the *assay for transposase-accessible chromatin using sequencing* (ATAC-seq) (Buenrostro *et al.* 2013). Whereas most epigenetic profiling approaches are specific to a given epigenetic mechanism, chromatin accessibility can be assayed by ATAC-seq without a priori knowledge of local epigenetic regulation mechanisms. In principle, ATAC-seq identifies open regions of the genome that are susceptible to DNA cleavage and tagging (tagmentation), which are catalyzed by a highly active Tn5 transposase (Buenrostro *et al.* 2015). Tagged DNA sequences are then amplified by PCR and identified using next-generation sequencing. ATAC-seq has been adopted widely as an efficient, low-input method for studying chromatin dynamics, nucleosome positioning, and transcription factor occupancy.

Genome-Editing Technologies

Genome-editing technologies based on site-specific DNA nucleases allow introduction of genetic modifications into almost any cell type and organism. To date, four major classes of customizable DNA binding proteins have been engineered for this purpose: meganucleases derived from microbial mobile genetic elements (Smith *et al.* 2006), zinc finger nucleases based on eukaryotic transcription factors (Miller *et al.* 2007; Urnov *et al.* 2005), transcription activator-like effectors from *Xanthomonas* bacteria (Christian *et al.* 2010; Miller *et al.* 2011), and the RNA-guided DNA endonuclease Cas9 (CRISPR-associated protein 9) from the type II bacterial adaptive immune system CRISPR (clustered regularly interspaced short palindromic repeats) (Cong *et al.* 2013; Mali *et al.* 2013). The most rapidly developing is the CRISPR/Cas9 system, which can be targeted to virtually any genomic location of choice via a short RNA guide. The CRISPR locus is typically composed of a clustered set of CRISPR-associated (Cas) genes and a series of repeat sequences interspaced by variable sequences (spacers) corresponding to sequences within foreign genetic elements (protospacers). A long pre-CRISPR RNA (crRNA) transcribed from the spacer-repeat CRISPR locus is processed into shorter crRNAs, which direct the nucleolytic activity of certain Cas enzymes to degrade target nucleic acids (Brouns *et al.* 2008; Hale *et al.* 2009).

Prokaryotes have evolved diverse RNA-mediated systems that use short crRNAs and Cas proteins to detect and defend against viral DNA elements (Bhaya *et al.* 2011; Marraffini and Sontheimer 2008; Wiedenheft *et al.* 2012). The guide sequence within these crRNAs can be easily replaced by a sequence of interest to retarget the Cas9 nuclease. A simple two-component system--consisting of Cas9 from the bacterial species *Streptococcus pyogenes* (Cong *et al.* 2013; Mali *et al.* 2013) or *Staphylococcus aureus* (Ran *et al.* 2015) and a fusion of the *trans*-activating crRNA-crRNA duplex to a single-guide RNA (sgRNA) (Jinek *et al.* 2012)--has been engineered for expression in eukaryotic cells and can achieve DNA cleavage at any genomic locus of interest. Hence, Cas proteins can be targeted to specific DNA sequences simply by changing the short specificity-determining part of the guide RNA (gRNA), which can be easily achieved in one cloning step (Heidenreich and Zhang 2016).

Several variants of the Cas9 nuclease have been adopted to help in genome editing. The first is wild-type Cas9, which can cleave double-stranded DNA at specific sites to form double-stranded breaks (DSBs). DSBs can be repaired by the cellular nonhomologous end joining (NHEJ) or homology-directed recombination (HDR) pathway (Burma *et al.* 2006; Kass *et al.* 2013; Maruyama *et al.* 2015). If a donor template with homology to the targeted locus is supplied, the DSB may be repaired by HDR. If an exogenous homology repair template is absent, the DSBs can be repaired by inducing insertion or deletion mutations (indels) via the NHEJ repair pathway (Bibikova *et al.* 2002). The second variant of the Cas9 nuclease is a mutant form known as Cas9D10A (Cong *et al.* 2013). It cleaves only one DNA strand and does not activate NHEJ. Instead, in the presence of a homologous repair template, DNA repairs are conducted via the HDR pathway only, resulting in reduced indel mutations (Qi *et al.* 2013). The third variant is a nuclease-deficient Cas9 (Qi *et al.* 2013). Mutations inactivate cleavage activity but do not prevent DNA binding (Jinek *et al.* 2012). Therefore, this variant can be used as either a gene silencing or a gene activation tool that "surgically" targets the desired region of the genome (Gilbert *et al.* 2013; Hu *et al.* 2014; Maeder *et al.* 2013; Perez-Pinera *et al.* 2013). It can also be applied to visualize repetitive DNA sequences with a single sgRNA or nonrepetitive locus using multiple sgRNAs fused to enhanced green fluorescent protein (Chen *et al.* 2013). Alterations of gene sequence or expression induced by the CRISPR/Cas9 system are displayed in Figure 1-7.

The CRISPR/Cas9 system has achieved widespread use in targeting genes in many cell lines and organisms, including humans (Mali *et al.* 2013), bacteria (Fabre *et al.* 2014), zebrafish (Gonzales and Yeh 2014), *C. elegans* (Hai *et al.* 2014), plants (Mali *et al.* 2013), frogs (Bhattacharya *et al.* 2015), yeast (Jacobs *et al.* 2014), flies (Li and Scott 2016), monkeys (Chen *et al.* 2015), rabbits (Yan *et al.* 2014), pigs (Hai *et al.* 2014), rats (Bao *et al.* 2015), and mice (Kalebic *et al.* 2016). In neuroscience research, the benefits of using CRISPR/Cas9 systems to study the nervous system are highlighted by several successful applications studying synaptic and circuit function, neuronal development, and diseases (Heidenreich and Zhang 2016). The delivery of Cas9 and sgRNA to target the methyl CpG binding protein 2 gene *Mecp2* in the adult mouse brain demonstrated phenotypes observed in classic *Mecp2*-mutant mouse models and patients with Rett syndrome (Swiech *et al.* 2015). Cas9-mediated deletion of common tumor-suppressor genes in the cerebellum and forebrain efficiently induced the formation of medulloblastoma and glioblastoma tumors, respectively (Zuckermann *et al.* 2015). Although NHEJ in postmitotic neurons has been demonstrated to be active, introduction of precise genetic mutations via HDR in the brain may remain challenging. It is commonly believed that HDR predominantly occurs in the S (synthesis) and G_2 (gap between DNA synthesis and mitosis) phases of the cell cycle, and HDR is therefore thought to be rare in nondividing cells, such as neurons (Heidenreich and Zhang 2016).

Transgenic and Gene-Targeting Techniques

Over the past few decades, progress in the development of molecular genetic methods has enabled the manipulation of genes in intact organisms, such as mice. The technologies have provided a powerful and useful tool that allows the study of gene function and promotes understanding of the molecular mechanisms of disorders of the brain and mind. The mouse genome is by far the most accessible mammalian genome for manipulation. Many successful procedures for introducing new genes, expressing elevated levels of genes, and eliminating or altering the function of identified target genes have been reported. Many mouse models produced by manipulating genes may be used in a variety of fields relevant to neuroscience. It is noteworthy, however, that behavioral studies in mice differ from those in rats, let alone primates, and several factors induce variability. As a result, interpretation of genetically induced behavioral alterations must be made with caution (Richter *et al.* 2009).

Generally, transgenic mice are those that express exogenous DNA because of the insertion of a gene into the mouse genome. Usually, that gene is randomly located within the mouse genome, often as several copies. The use of transgenic mice has represented a major strategy for the investigation of genetic questions following research establishing the feasibility and reproducibility of stably introducing DNA by microinjection into individual male mouse embryos (Markert 1983). In DNA constructs used for the generation of transgenic mice, the gene of interest is located 3' to promoter sequences to produce a desired distribution of gene expression. Selection of the promoter is the most important consideration in generating transgenic mice. Some promoters, such as platelet-derived growth factor (PDGF), thy1 (a cell surface glycosylphosphatidylinositol-linked glycoprotein), prin (PrP), neuron-specific enolase (NSE), and glial fibrillary acidic protein (GFAP), have demonstrated the ability to direct high-level expression of exogenous genes in brain and/or in the neurons of mice (Hsiao *et al.* 1996; Nolte *et al.* 2001; Sturchler-Pierrat *et al.* 1997; Yang *et al.* 2004; Zhu *et al.* 2001). This level of expression can be modified by incorporation of a "tet-on" or "tet-off" vector into the desired inserted gene. Depending on the nature of the switch (on or off), the mouse will express the gene of interest when ingesting (or taken off) doxycycline.

Gene targeting refers to the homologous recombination that occurs between a specifically designed targeting construct and the chromosomal target of interest, in which recombination at the target locus leads to replacement of the native target sequence with a construct sequence. The method enables the precise introduction of a mutant into one of many murine genes and has proven invaluable in examining the roles of gene functions in complex biological processes. Most of the target constructs are used to disrupt a target and to eliminate gene function (conventional "knockout"). Generally, a gene-targeting construct that contains positive-negative selection markers is prepared such that the target gene is interrupted by the gene for neomycin resistance, which also serves as a positive selection marker, and a thymidine kinase (TK) gene is adjacent to either one or both ends of the homologous genomic sequence for negative selection (Gusella *et al.* 1983). The positive-negative deletion scheme is employed to enrich for homologous recombination.

The targeting construct is often introduced into mouse embryonic stem cells by electroporation. Cells that fail to integrate the targeting construct into the genome are killed by application of neomycin in the culture medium (positive selection). The majority of the remaining cells, in which the entire construct (including the TK gene) inserts randomly, will die as a result of the incorporation of ganciclovir or fialuridine (inactive thymidine analogs), either of which blocks DNA synthesis. Homologous recombinant clones that do not contain the TK gene are used to prepare chimeric mice. Cells from these clones are microinjected into the fluid-filled cavity of 3.5-day-old embryos at the blastocyst stage. The injected embryos are then surgically transferred into the uterus of pseudopregnant females. These animals will give birth to chimeric mice. Breeding can be used to generate mice that are heterozygous and homozygous for the mutation. Homozygous mutants may express the gene of interest in any cell of the body (Figure 1-8).

Use of Mutant Mice in Studies of Brain Disease

Transgenic mice produced by this method are generally gain-of-function mutants, because the transgene is designed either to express a novel gene product or to disrupt a normal gene product by expressing a "dominant-negative" alternative. It is also possible to put a DNA fragment in the opposite direction and hence to produce transgenic mice expressing antisense RNA, which will reduce gene function (Jouvenceau *et al.* 1999; Katsuki *et al.* 1988). Expression of mutant amyloid precursor protein (APP) or presenilin 1 (PS1) or mutant forms of tau in mice has generated many animal models that may be related to Alzheimer's disease. These transgenic mice have facilitated studies of the pathogenesis, molecular mechanisms, and behavioral abnormalities of Alzheimer's disease (Bornemann and Staufenbiel 2000; Janus *et al.* 2001). Nevertheless, because the transgene integrates into the mouse genome randomly and often exists as several copies, the interpretation of studies with transgenic mice is difficult.

(A) Producing chimeric mice. First, a mutant allele is produced by replacing the coding exons of the desired gene with a neomycin (neo) cassette and transferred into embryonic stem (ES) cells. Second, genetically altered ES cells are reintroduced into a developing blastocyst, where they contribute to the developing embryo. **(B) Breeding chimeric mice.** When the germ cells of the resulting chimeric mouse (chimera) are ES cell-derived (germ-line mutation), the heterozygotes (+/[?]) can be produced by breeding. One-half of the offspring will be heterozygous. The heterozygous animals may be bred to produce homozygous mice ([?]/[?]). TK = thymidine kinase; WT = wild type.

Experiments with knockout mice have provided novel insights into the functional roles of neuronal genes and, in some cases, animal models relevant to brain disorders. The targeted mutants in a gene of interest, however, can sometimes lead to embryonic lethality in mice, thus obscuring the role of that gene in a specific tissue or in the adult. Furthermore, in some instances, genes related to the eliminated gene undergo increased expression in the knockout mice. In this case, the related gene compensates for the gene of interest and yields a phenotype that resembles the "normal" animal. Such compensation has been seen for the knockouts of the axonal microtubule-associated protein tau (Takei *et al.* 2000).

Tissue-Specific Gene Manipulation

A tissue-specific mechanism for gene targeting is the Cre-loxP system. Both the Cre (cyclization recombination) recombinase and loxP sequences are derived from the P1 bacteriophage, which uses this recombination system in its life cycle to maintain the phage genome as a unit copy plasmid in the lysogenic state. The Cre-loxP system enables the specific manipulation of DNA based on the direction and location of the two loxPs. As a member of the integrase superfamily of site-specific recombinases, the Cre recombinase does not require any host cofactors or accessory proteins to mediate loxP-specific recombination. In most cases, loxP sites are placed in the same chromosome in direct repeat positions so that the intervening DNA sequence can be deleted. The loxP sites can also be placed in different chromosomes to promote recombination between different chromosomes, or they can be placed in an inverted position in the same chromosome to create a switch to inactivate and activate genes of interest (Bouabe and Okkenhaug 2013).

For conditional site-specific genome modification, two mouse lines are usually needed: 1) mice that have the DNA sequence of interest flanked by loxP sites (or "floxed"), which can be achieved by introducing loxP sites into the genomic locus of interest by homologous recombination as described in the previous paragraph, and 2) Cre recombinase transgenic mice, in which Cre is expressed under the control of a promoter that is active in specific cell types or tissues, or in which Cre is transiently expressed under the control of a promoter that is active at a particular developmental stage of tissues or cells. Cre expression can also be controlled temporally, by introducing an element into the promoter, which requires a ligand, such as a drug, for induction. When mice carrying such "floxed" genes are mated with transgenic mice expressing Cre recombinase, the target gene of the offspring is modified through Cre action in the cell types or tissues where Cre is expressed, or in the cell or tissue when the mouse is treated with a drug, such as tamoxifen (Bouabe and Okkenhaug 2013; Friedel *et al.* 2011; Liu *et al.* 2014). Studies in which the *N*-methyl-D-aspartate (NMDA) receptor gene *NR1* was deleted from specific hippocampal loci using Cre-loxP recombination technology reveal that a regional variation in NMDA receptor-dependent synaptic plasticity of postnatal excitatory neurons is required for specific aspects of hippocampal learning and memory (McHugh *et al.* 2007; Nakazawa *et al.* 2003).

Optogenetics and Chemogenetics

Optogenetics is a technique for parsing and manipulating specific neural circuits (Figure 1-9). Since its inception, optogenetics has been adapted both swiftly and broadly (Deisseroth 2015) and applied to psychiatric research (Shirai and Hayashi-Takagi 2017). Optogenetics makes use of microbial (bacterial and algal) opsins that have properties of both chromophores and ion channels. These molecules are unlike the metazoan rhodopsins, which convert light into an intracellular signal through a G protein-coupled receptor. Instead, these proteins (channelopsins and bacteriorhodopsin) form ion channels, and there are naturally occurring molecules that subserve both excitatory (Na^{+}) and inhibitory ($\text{Cl}^{[?]}$) functions, as activated by the channels.

(I) Direct stimulation of neuronal cell bodies is achieved by injecting virus at the target region and then implanting a light-delivery device above the injected region. Even this simple experiment can provide specificity with viruses that will not transduce afferent axons and fibers of passage. **(II)** Additional cell-type specificity is attained either by cell-type-specific promoters in the viral vector or via a recombinase-dependent virus, injected in a transgenic animal expressing a recombinase such as Cre in specific cells, leading to specific expression of the transgene only in defined cell types. **(III)** Projection (axonal) targeting is achieved by viral injection at the region harboring cell bodies, followed by implantation of a light-delivery device above the target region containing neuronal processes from the virally transduced region; in this way, cell types are targeted by virtue of their projections. **(IV)** Projection termination labeling is a more refined version of projection targeting, in which cells are targeted by virtue of synaptic connectivity to the target region, with likely exclusion of cells whose axons simply pass through the region. Transcellular labeling using a recombinase-dependent system is shown. Viruses expressing Cre fused to a trans-neuronal tracer (lectin) are delivered at the synaptic target site, and a Cre-dependent virus is injected into the region with cell bodies. Cells that project to the Cre-injected area express the Cre-dependent virus and become light sensitive. Transcellular labeling can also be achieved with axon terminal-transducing viruses, although without control over the postsynaptic cell type. **(V)** Expression of two opsins with different characteristics in one brain region using a combination of promoter-or Cre-based approaches. Light delivery to the somata is performed using two different wavelengths designed to minimize cross-activation. **(VI)** Projections from two different brain regions are differentially stimulated with two wavelengths matched to the respective opsins expressed upstream.

The ingenious application that initially launched optogenetics toward worldwide adaptation was an engineered system that allowed both specificity of expression and specificity of excitation. This tool allowed an investigator to inject a virus encoding a channelrhodopsin activated by a specific wavelength of light and a targeting vector restricting expression to a certain class of cells (e.g., serotonergic) within a defined brain region. Introduction of a fiberoptic cable into the area of injection permitted the activation of the channelrhodopsin (and the subsequent activation or inhibition of the neuron containing that rhodopsin) by light. As the technique was further refined, channel opsins responsive to different wavelengths were expressed so that, depending on the wavelength used, different cells within a similar anatomic locus could be selectively activated or inhibited. The readout from such experiments could be anything from electrophysiological to behavioral.

A similar technology uses chemogenetics to control the activity of neuronal subpopulations in transgenic animal models. In chemogenetics, Cre-inducible viral vectors can be used to express *designer receptors exclusively activated by designer drugs* (DREADDs). Inhibitory or excitatory DREADDs (Armbruster *et al.* 2007; Krashes *et al.* 2011) are pharmacologically activated by the biologically inert ligand clozapine-*N*-oxide (CNO), where upon binding, CNO triggers an inhibitory (G_i) or excitatory (G_q) or intracellular signaling (G_s) cascade driven by a mutant G protein-coupled receptor (GPCR). As optogenetic and chemogenetic approaches continue to be refined, the ability to translate from cells to circuits to behavior will increase in both complexity and resolution.

Proteomics and Beyond

The large-scale analysis of proteins in biological systems is critical to understanding the functional output of transcriptomic programs. Since mRNA levels can only approximate protein levels and the activity of proteins is often regulated through posttranslational modifications including phosphorylation and ubiquitination, proteomic analyses provide important insights that would otherwise be missed using genomic, epigenetic, and transcriptomic approaches. Increasingly, bioinformatic tools, including machine learning, are used to integrate and analyze large datasets produced through "multi-omics" to gain a more thorough understanding of complex biological systems and disease states.

Proteomics is a broad discipline where protein structure, function, interactions, posttranslational modifications, or expression levels are interrogated. Generally, protein expression profiling involves the ionization and analysis of proteins by mass spectrometry.

Conclusion

Increased knowledge of the human genome and advances in the methodology for genetic manipulation are continuously combining with advances in neurobiology. We are accumulating knowledge of human gene mutations and their possible connections to neurological and psychiatric diseases at a rapid pace. Rationally designed genome-based therapeutics are, in particular, emerging for monogenic (single gene locus-associated) disorders or cancers with single drivers. Increasing attention is today given by researchers to many gene regulatory mechanisms and to regions of the genome outside the classic protein-coding genes. However, the complexity of the genome, and its regulation, continues to pose challenges to our understanding of the true pathogenic mechanisms for complex polygenic diseases.

Most if not all drugs, as well as other types of treatments, for psychiatric disorders work initially by modifying the process of synaptic transmission. As first described by Cajal and Sherrington, nerves are able to communicate with each other even though there is a very small space, termed the synapse, separating them. This space is about 30 nanometers wide--about 1/1,000 the width of a human hair. In view of such a small space, it is not surprising that there was an intense debate about the mechanism of synaptic transmission. One school of thought held that the mechanism was "electrical," whereby the action potential invading the presynaptic nerve terminal could directly activate the neuron on the other side of the synapse, the postsynaptic one. The other school of thought held that it was "chemical," such that chemicals were released from the activated presynaptic neuron, diffused across the synapse, and either activated or inhibited activity in the postsynaptic neuron by acting on receptors located on it. This debate has been referred to, somewhat facetiously, as "war of the soups versus sparks" (Valenstein 2005). There is now essentially universal agreement that the process of synaptic transmission is chemical in nature, at least in the mammalian central nervous system (CNS). Not surprisingly, the chemicals involved are called *neurotransmitters*. In this chapter we focus on the neurotransmitters considered to be involved in psychiatric disorders and their treatment as well as the receptors by which they produce their effects. Figure 2-1 shows the structures of neurotransmitters discussed in this chapter.

Neurotransmitters

Criteria have been established that must be fulfilled for a chemical to be considered a neurotransmitter:

1. The chemical is present (synthesized and stored) in neurons.
2. The chemical is released from neurons.
3. When administered exogenously, the chemical mimics precisely the action of the endogenously released chemical.
4. Specific mechanisms exist for removing the chemical from the synapse to terminate its activity there.

Many chemicals have been identified as neurotransmitters, and the numbers have increased as the definition of a neurotransmitter has been extended to include neuromodulators and neurohormones. And not only are there multiple neurotransmitters, but for each neurotransmitter, there are many different receptors. With 100 billion neurons and 10-to 50-fold more glial cells, it is no wonder that the human brain is considered to be the most complex organ in the body and even the most complex structure in the world.

The different transmitters and their receptors allow for specificity in modifying synaptic transmission. This contrasts with the process of neuronal conduction, which is similar for all neurons. Alteration of neuronal conduction (e.g., via administration of general or local anesthetics) produces nonspecific effects. By contrast, more specific effects can be produced by modifying the actions of different neurotransmitters, which is desirable when considering the treatment of psychiatric disorders.

Receptors

Intercellular communication is a requirement for multicellular organisms to maintain homeostasis and to respond appropriately to the environment. Receptors are proteins that allow cells to respond to chemical signals from other cells and from the environment, such as those carried by neurotransmitters, hormones, and sensory stimuli. In general, such signals lead to a conformational change in the receptor protein that allows the receptor to alter cellular function. In the CNS, receptors can be found on the plasma membrane or in intracellular compartments in both neurons and glial cells (e.g., oligodendrocytes, astrocytes, microglia). Most neurotransmitter receptors are cell surface receptors and consist of three major classes: ionotropic receptors, seven-transmembrane-spanning (also known as G protein-coupled) receptors, and tyrosine kinase receptors. As will be discussed in more detail below, the conformational change in ionotropic receptors in response to neurotransmitter binding results in a change in ion permeability, thereby altering (increasing or decreasing) cell excitability. Neurotransmitter activation of receptor tyrosine kinases increases the kinase activity of the protein, resulting in phosphorylation of the receptor itself (autophosphorylation) along with phosphorylation

of secondary signaling molecules that lead to changes in cell function. Conformational changes in seven-transmembrane-spanning receptors by neurotransmitter binding allow the receptors to interact with secondary molecules (transducers), such as guanine nucleotide-binding proteins (G proteins), arrestins, and others, to regulate cellular function. An excellent resource for detailed information on the many subtypes of cell surface receptors and neurotransmitters (along with many other important pharmacological components) that is updated regularly can be found at the website of the International Union of Basic and Clinical Pharmacology/British Pharmacological Society (IUPHAR/BPS) Guide to Pharmacology (www.guidetopharmacology.org).

Ionotropic Receptors

The first class of receptors described in this chapter are ion channel (or ionotropic) receptors. These receptors are quite literally pores in the cellular membrane that are permeable to specific ions. When these receptors/pores are open, ion channels permit the passive diffusion of ions down their concentration (and electrical) gradient. The beginning of our understanding of ion channel function came from Alan Hodgkin and Andrew Huxley, who worked together in the 1940s and 1950s and received a Nobel prize for their research (Hodgkin and Huxley 1952). Using the giant axon of a squid, they measured the membrane potential of a neuron and recorded the first intracellular action potential (Hodgkin and Huxley 1952). These and subsequent studies revealed that the concentrations of ions inside and outside of a neuron are not in equilibrium. Rather, in the CNS, the concentrations of Na^+, Ca^{2+}, and $Cl^{[?]}$ are much higher outside the cell, whereas the opposite is true for the concentrations of K^+. This concentration gradient is generated, in part, by the plasma membrane sodium-potassium adenosine triphosphatase (Na^+/K^+ ATPase) and provides the foundation for ionotropic receptor signaling (Figure 2-2). Ligand-gated ion channels undergo a conformational change when a molecule (ligand) binds, resulting in the opening of a pore in the membrane. If the ionotropic receptors are permeable to Na^+ or Ca^{2+}, positively charged ions will flow down the concentration gradient into the neuron, resulting in depolarization. Conversely, opening of ionotropic receptors permeable to K^+ or to $Cl^{[?]}$ leads to hyperpolarization due to an efflux of positive or an influx of negative ions, respectively (see Figure 2-2). Ligand-gated ion channels are described later in the chapter and include receptors for glutamate (e.g., the NMDA [*N*-methyl-D-aspartate] receptor; see "Glutamatergic System"), g-aminobutyric acid (e.g., the $GABA_A$ receptor; see "GABAergic System"), acetylcholine (e.g., the nicotinic acetylcholine receptor; see "Cholinergic System"), and serotonin (e.g., the 5-hydroxytryptamine [5-HT] type 3 [$5\text{-}HT_3$] receptor; see "Serotonergic System").

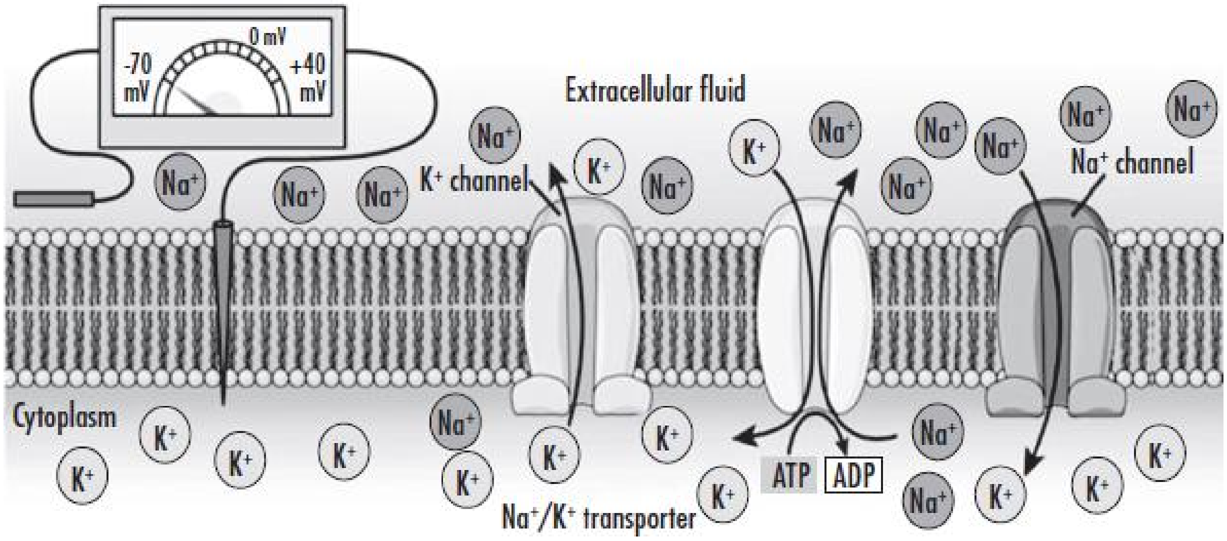

FIGURE 2-2. Ion channel function in the CNS.

See Plate 4 to view this figure in color.

The plasma membrane Na^+/K^+ ATPase establishes a concentration gradient in the CNS, pumping Na^+ out and K^+ into the cell. Ion channels permit the passive diffusion of ions across the plasma membrane. Thus, opening of Na^+ channels depolarizes--and of K^+ channels hyperpolarizes--a neuron. ADP = adenosine diphosphate; ATP = adenosine triphosphate; mV = millivolt.

The ability to move ions across the membrane stems from the physical properties of the channel. In the case of ionotropic receptors, various subunits of the receptor combine in the membrane to form a pore. There are often multiple receptor subunits for a single class of ionotropic receptor. For example, the $GABA_A$ receptor is assembled as a pentameric structure from at least 19 different subunits, resulting in distinct functional and anatomical distributions (Olsen and Sieghart 2009). This heterogeneity provides a system with considerable flexibility. For example, there is research into the potential development of $GABA_A$ receptor modulators that produce an anxiolytic effect devoid of sedation, or as a novel class of antidepressant medication by targeting distinct subunits present in selected brain regions. The benefit of targeting ionotropic receptors is that their effects are rapid (ion channels open and close within milliseconds) and regulate both fast excitatory and inhibitory synaptic signaling in the CNS. As discussed in the "Neurotransmitter and Neuropeptide Systems" section later in this chapter, many of the classical neurotransmitters (e.g., monoamines) exert their effects on a slower time scale and are therefore often considered to be modulatory.

G Protein-Coupled Receptors

As the name *G protein-coupled receptor* (GPCR) implies, these receptor proteins couple to heterotrimeric guanine nucleotide-binding proteins (G proteins). However, it is now well established that GPCRs can interact with and signal via a variety of signaling partners, such as G proteins, arrestins, and others. For this reason, it may be more appropriate to call these receptors *seven-transmembrane-spanning receptors*; nevertheless, the term *GPCR* is entrenched in the literature.

GPCRs are the largest family of cell surface receptors and are a major target for pharmaceuticals (Wacker *et al.* 2017), especially in psychiatry (Catapano and Manji 2007; Grammatopoulos 2017). In humans, there are approximately 800 GPCRs, which can be subdivided into five families (Rhodopsin, Secretin, Glutamate, Adhesion, and Frizzled) based on amino acid sequence homology. More than half of these receptors are involved in processing sensory information (light, olfaction, taste, and pheromones), and the vast majority of these (~ 400) are olfactory receptors. The remaining receptors (~ 350) are activated by a wide variety of molecules--ranging in size from ions (e.g., calcium) to proteins (e.g., luteinizing hormone)--and include neurotransmitters important for CNS function, such as glutamate, GABA, norepinephrine, dopamine, serotonin, and acetylcholine.

The role of a GPCR is to detect the presence of an extracellular signaling molecule and subsequently change cellular function. GPCRs are involved in regulating a broad array of physiological functions and behaviors, which makes them ideal as targets for drugs. In fact, about 35% of U.S. Food and Drug Administration (FDA)-approved drugs target GPCRs (Insel *et al.* 2019). However, because the FDA-approved drugs act on fewer than 50% of the nonsensory GPCRs (Yang *et al.* 2021), there is considerable opportunity for development of new drugs to target other GPCRs.

All GPCRs have similar structural characteristics and consist of a single polypeptide chain of amino acids, with an extracellular N-terminus and an intracellular C-terminus, that traverse the membrane seven times (Figure 2-3). The well-conserved transmembrane hydrophobic domains are alpha helices, consisting of 25-35 amino acids each. These transmembrane domains are connected by three extracellular and three intracellular loops of amino acids that vary considerably in length. Due to posttranslational modifications, some GPCRs (~ 70%) have a fourth intracellular loop as a result of reversible palmitoylation of cysteine residues in the C-terminal domain (Naumenko and Ponimaskin 2018). Palmitoylation--and other posttranslational

modifications (e.g., phosphorylation, acylation, glycosylation, ubiquitination, sumoylation) of amino acids in various parts of a GPCR--can markedly alter signaling and trafficking of the targeted receptor (Patwardhan *et al.* 2021).

The CXCR1 consists of characteristic seven-transmembrane helices (TM1-TM7) connected by three extracellular loops (e1-e3) and three intracellular loops (i1-i3). The disulfide bond between the cysteine residues of e1 and e2 is also characteristic of GPCRs.

GPCRs are activated by a wide variety of extracellular chemical signals that bind to and stabilize an active conformation of the receptor capable of interacting with intracellular signaling molecules (transducers), including G proteins and arrestins. Ligands bind to an extracellular-facing binding pocket (known as the orthosteric binding site), the location of which differs widely for different receptors. For some receptors (e.g., biogenic amine receptors such as serotonin, norepinephrine, and dopamine), the orthosteric binding pocket is located within the transmembrane domains. For others, the ligand binds to a pocket in the N-terminal domain (e.g., glutamate family), to amino acids in the extracellular loops, or to both the N-terminal domain and extracellular loops.

If a ligand has positive intrinsic efficacy (i.e., an agonist), ligand binding results in receptor activation. Receptor activation involves reorientation of transmembrane helices (outward movement of transmembrane domain 6), which promotes interaction of the receptor with its transducing partners (see "GPCR transducing proteins") (Zhou *et al.* 2019), thereby leading to changes in cell function. It also should be pointed out that GPCRs can adopt an active conformation spontaneously in the absence of the binding of an activating ligand. This type of ligand-independent activation is called *constitutive receptor activity* and will be discussed in more detail below (see "Constitutive Receptor Activity").

In addition to orthosteric binding, ligands can bind to other sites on a receptor that are referred to as *allosteric* binding sites ("allo" means "other"). Such ligands are called *allosteric modulators* or *allosteric regulators*. Allosteric modulators act by changing the conformation of the receptor in a way that causes the ligand binding affinity and/or intrinsic efficacy to be altered (Gentry *et al.* 2015; Kenakin 2021; Wenthur *et al.* 2014). In a way, a receptor with an allosteric modulator bound is a different receptor. The conformational change in the receptor produced by allosteric ligand occupancy can differentially alter the affinity and/or the intrinsic efficacy of an orthosteric ligand in a ligand-dependent manner (i.e., the allosteric effect can be different for different ligands). This is known as *probe dependence* (wherein the orthosteric ligand is considered the "probe"). Allosteric ligands that increase orthosteric ligand affinity and/or intrinsic efficacy are called *positive allosteric modulators* (PAMs). Conversely, those that decrease orthosteric affinity and/or intrinsic efficacy are referred to as *negative allosteric modulators* (NAMs). It is important to note that because of probe dependence, the designation as PAM or NAM is dependent on the specific orthosteric ligand. Thus, the same allosteric modulator can be a NAM for one orthosteric ligand but a PAM for another. Because allosteric regulators do not block the orthosteric binding site, they "fine-tune" receptor function, allowing for the natural pattern/rhythm of endogenous agonist activity. Also, adverse effects associated with complete abolition of orthosteric binding to the receptor are avoided; thus, allosteric ligands are considered to be safer than orthosteric drugs. Because allosteric binding sites on a receptor are less conserved than orthosteric sites, allosteric ligands are also more selective than orthosteric ligands and can often distinguish between highly homologous receptors. There is great optimism for the discovery of new therapeutic medications that are allosteric modulators.

Unlike other cell surface receptors where the receptor is itself an effector (e.g., ligand-gated ion channels, receptor tyrosine kinases), activated GPCRs by themselves do not change cellular function. GPCRs must interact with a partner molecule (a transducer) in order to signal. Perhaps the best-studied transducers are the heterotrimeric G proteins.

GPCR Transducer Proteins: G Proteins and Arrestins

G proteins. The G proteins that couple to GPCRs consist of three subunits (heterotrimeric): alpha (a), beta (b), and gamma (g). In general, the b and g subunits are tightly bound to each other and form a functional unit that is commonly referred to as the b/g subunit. In humans, there are 21 a, 6 b, and 12 g subunits that combine to form a wide variety of heterotrimers. The a subunits bind guanine nucleotides, such as guanosine diphosphate (GDP) and guanosine triphosphate (GTP)--hence the name *guanine nucleotide-binding protein*. In addition to binding guanine nucleotides, the a subunit is also an enzyme that hydrolyzes GTP (GTPase) to remove the terminal phosphate, resulting in the formation of GDP. As transducer proteins, G proteins relay the signal from an activated GPCR to cellular effector proteins that are responsible for effecting a change in cell function. G proteins regulate a wide variety of effectors, including adenylyl cyclases, phospholipase C, various kinases, scaffold proteins, and ion channels (Figure 2-4).

G proteins are divided into four families based on the identity of the a subunit, and each subfamily has multiple members (Table 2-1). Although initially thought to be an inert holding protein for a subunits, the b/g subunit is now recognized to also play a major role in regulating cellular effectors, including ion channels, adenylyl cyclases, phospholipases A and C, G protein receptor kinase 2, and phosphoinositide 3-kinase, among others (Smrcka and Fisher 2019).

G protein activation cycle. When a GPCR adopts an active conformation, either due to constitutive receptor activity or in response to agonist binding, it initiates a sequence of events leading to G protein activation. At rest, the G protein exists as a heterotrimer, with GDP bound to the guanine nucleotide binding site of the a subunit, which itself is bound to the b/g subunit (Figure 2-5A). Upon agonist binding (Figure 2-5B), the active GPCR conformation allosterically regulates the conformation of the a subunit such that the affinity for GDP decreases and the affinity for GTP increases (Figure 2-5C). This conformation change in the a subunit results in a GDP-to-GTP exchange, wherein GTP replaces GDP in the guanine nucleotide binding domain (Figure 2-5D). In addition, G protein dissociates from the receptor and the b/g subunit dissociates from the GTP-bound a subunit. At this point, the G protein is "active," with GTP bound to the a subunit and the b/g subunit separated from the a subunit, and both separated from the receptor (Figure 2-5E). It should be noted that for some G proteins, activation may involve rearrangement rather than dissociation of the a and b/g subunits (Chung and Wong 2021). The GTP-bound a and the b/g subunits function to regulate their target effector's activity (Figure 2-5F). Activated G proteins can increase or decrease the activity of effectors, depending on the specific characteristics of the G protein. In some cases, the a and b/g subunits co-regulate the activity of the same effector (e.g., adenylyl cyclases and phospholipase Cb). It is generally accepted that a single GPCR in an active conformation can sequentially activate multiple G proteins. This process would contribute to amplification of the signal.

Termination of G protein activity results from the conversion of bound GTP to GDP by the GTPase activity of the a subunit (Figure 2-5F). This enzymatic inactivation process is relatively slow (with turnover rates ranging from 0.1 to 4.0 min$^{[?]1}$, depending on the G protein), which allows time for the regulation of effector activity and further amplification of the signal. For example, a single activated GPCR, signaling through G_s, could result in hundreds of cyclic adenosine monophosphate (cAMP) molecules being formed from increased enzymatic activity of adenylyl cyclase. Upon hydrolysis of GTP to GDP, the inactive a and b/g subunits reform (Figure 2-5A) and can be reactivated if the receptor remains in an active conformation.

Arrestins. In addition to signaling via G proteins, GPCRs can also couple to other cellular transducer molecules to alter cell function. The arrestin family of proteins is perhaps the best studied of these non-G protein transducers. There are four members of the arrestin family (arrestin 1-4). Arrestins 1 and 4 are found primarily in the photoreceptor cells of the retina, whereas the other nonvisual arrestins (2 and 3) are ubiquitously expressed and are also referred to as b-arrestin-1 and b-arrestin-2, respectively. Arrestins bind preferentially to GPCRs in an active conformation, and this interaction changes the conformation of the arrestin molecule, which, by acting as a scaffold, influences the activity of a wide variety of cellular signaling systems (Peterson and Luttrell 2017). Most notably, arrestin signaling activates the mitogen-activated protein kinases (MAPKs) extracellular signal-regulated kinase 1/2 (ERK1/2), c-Jun N-terminal kinase (JNK), and p38 MAPK, all of which can regulate gene transcription.

Constitutive Receptor Activity

GPCRs can spontaneously adopt an active conformation that can regulate cellular signaling cascades in the absence of an agonist ligand. This process is called *constitutive receptor activity*. As is true for all proteins, GPCRs are not rigid, static structures, but are in constant motion, changing conformations as a result of thermal energy. Given this state of continuous conformational flux, it should come as no surprise that a GPCR can adopt an active conformation. The conformational flexibility of a receptor depends on the number and strength of intramolecular constraints (e.g., bonds, such as hydrogen bonds, van der Waals forces, and electrostatic interactions). Depending on their amino acid sequences, some receptors are more conformationally flexible than others and thus may exhibit higher levels of constitutive activity. At any point in time, some percentage of the receptor population may be in an active, signaling conformation, which contributes to basal cellular activity. It should be noted that the level of constitutive receptor activity is dependent not only on the number of receptors in a population that are active at any point in time but also on the efficiency of receptor-effector coupling, which is strongly influenced by the phenotype of the cell in which the receptor is expressed. For example, for a specific receptor, constitutive receptor activity will be higher in cells with high densities of receptor, transducer, or effector expression, all of which can change with physiological state or disease.

The finding that receptors can signal in the absence of an activating ligand led to the discovery that binding of some ligands can reduce this constitutive activity by stabilizing an inactive conformation (Berg and Clarke 2018). Such ligands are called *inverse agonists* because they have an effect opposite to that of an agonist ligand that stabilizes an active conformation. Thus, in pharmacology we now have five classes of drugs (Figure 2-6): 1) full agonists (which produce maximal effects); 2) partial agonists (which produce less-than-maximal effects); 3) antagonists (which have no to minimal effects of their own but block the effects of agonists); 4) full inverse agonists (which reduce "basal" activity); and 5) partial inverse agonists (which produce less-than-maximal reduction in basal activity). Because constitutive receptor activity depends on cell phenotype, many of the atypical antipsychotic medications that were previously thought to be antagonists have been shown to have inverse agonist properties (Meltzer 2017; Sullivan *et al.* 2015). Although there is considerable optimism about the possible therapeutic benefits of inverse agonists for neuropsychiatric disorders, their clinical utility has yet to be fully realized. As of mid-2023, the FDA has approved only two drugs whose therapeutic efficacy was attributed to inverse agonism. In 2016, the 5-HT$_{2A}$ inverse agonist pimavanserin (Nuplazid) was approved by the FDA for treatment of psychosis associated with Parkinson's disease (Cummings *et al.* 2014).

Functional Selectivity

An important characteristic of GPCRs is that their conformational change can be dependent on the structure of the ligand that binds to them. These ligand-dependent conformations can result in differential, ligand-dependent regulation of various cellular signaling pathways coupled to the receptor. This process is known as *functional selectivity* or *biased agonism* (Berg and Clarke 2018; Kenakin 2021; Urban *et al.* 2007). That drugs can display functional selectivity indicates that drugs have more selectivity than that afforded by differential affinity for different receptor subtypes. Different drugs acting at the same receptor subtype can elicit different cellular responses. For this reason, new drugs may be developed that display better therapeutic efficacy with reduced adverse-effect liability. There are high hopes that ligand-dependent signaling will be of immense value for pharmacotherapy for neuropsychiatric conditions and other diseases. The efficacy of aripiprazole (Abilify) as an antipsychotic medication has been attributed to its functional selectivity at dopamine D_2 and other receptor subtypes (de Bartolomeis *et al.* 2015; Tuplin and Holahan 2017).

Desensitization (homologous and heterologous). Signaling by GPCRs via G proteins to effectors is terminated when the agonist that activated the GPCR dissociates from the receptor and is removed by diffusion or metabolism. However, GPCR signaling can also be terminated/reduced even if the agonist remains bound to the receptor and the receptor remains in an active conformation. This process, wherein GPCR signaling is terminated or reduced with prolonged or repeated agonist exposure, is called *desensitization* or *tachyphylaxis* (Hausdorff *et al.* 1990; Kelly *et al.* 2008; Rajagopal and Shenoy 2018). It should be noted that "prolonged" can mean time periods of seconds to days (Figure 2-7). In addition to that induced by agonist exposure, desensitization can also result from constitutive receptor activity (Berg and Clarke 2018). There are several cellular mechanisms for desensitization. Perhaps the best-studied mechanism involves the binding of an arrestin molecule to the activated receptor. As illustrated in Figure 2-8, following activation, the receptor becomes phosphorylated by G protein receptor kinase (GRK). This phosphorylation increases the affinity for arrestin, resulting in the binding of arrestin to the receptor. Through steric hindrance, arrestin binding interferes with the coupling of G proteins to the receptor, thereby stopping (arresting) G protein signaling. As discussed above (see "Arrestins"), arrestin can also act as a transducer molecule to mediate signaling. In this way, arrestin binding to an activated GPCR can switch signaling from G protein pathways to arrestin-mediated pathways in a time-dependent manner. Because the arrestin molecule also has a clathrin-binding domain, the arrestin-bound receptor becomes associated with clathrin-coated pits in the cell membrane and undergoes internalization, further reducing GPCR activation by extracellular ligands. Internalized receptors can undergo degradation (a process called *downregulation*) or can be dephosphorylated and recycled back to the cell membrane. If receptors are downregulated, recovery of responsiveness requires synthesis of new receptors. Recently, signaling mediated by internalized GPCRs has been reported (Eichel and von Zastrow 2018), which represents an understudied yet highly interesting function of GPCRs that may yield new approaches for therapeutic drug development.

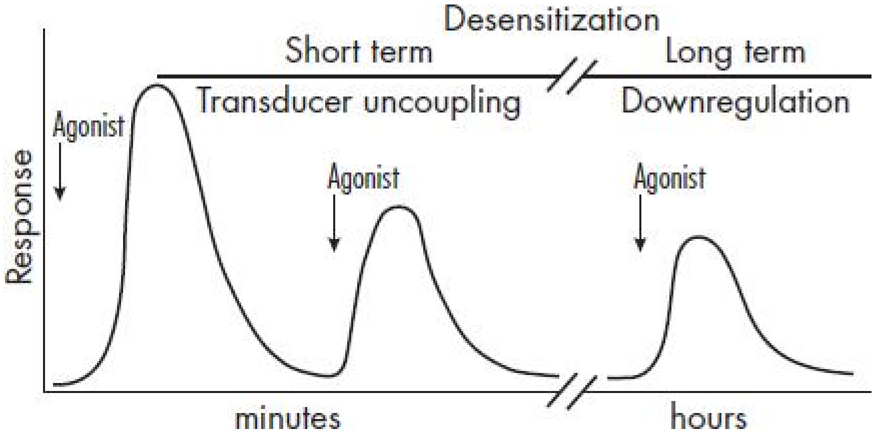

FIGURE 2-7. Time-dependent loss of responsiveness.

Acute and prolonged phases of desensitization: Repeated stimulation with an agonist results in a decreased response over a time frame of minutes (transducer uncoupling or acute desensitization). Over hours to days, repeated stimulation may result in decreased receptor expression at the plasma membrane (downregulation or prolonged desensitization). Together these processes contribute to the phenomenon of tachyphylaxis.

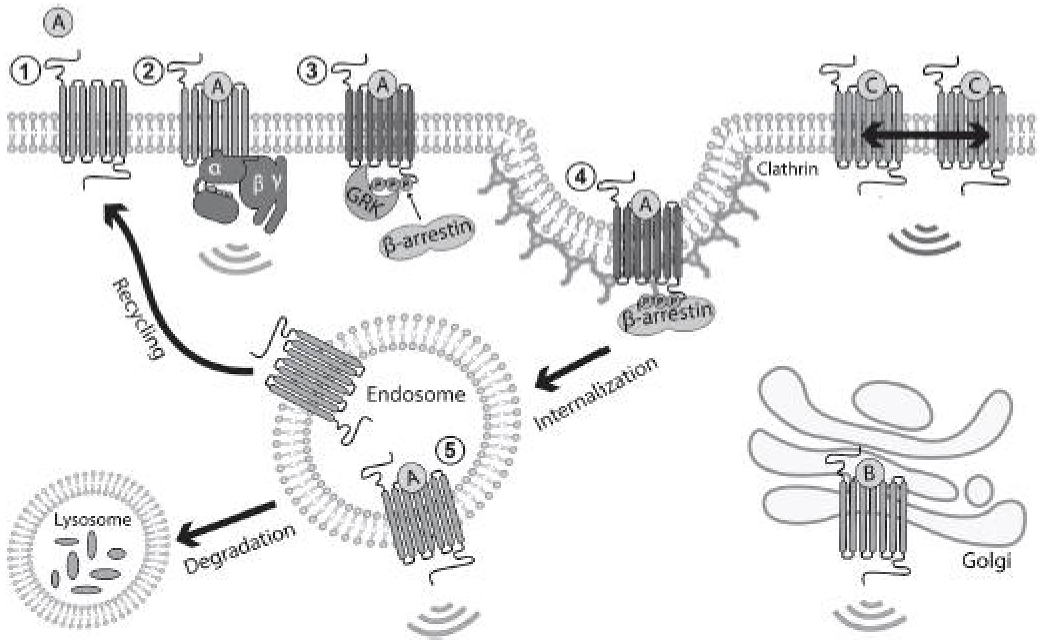

FIGURE 2-8. Agonist-induced signaling and trafficking of opioid receptors.

See Plate 7 to view this figure in color.

Inactive opioid receptors (*gray*) become activated (*green*) after binding to an agonist (drug A; steps 1-2). The active receptor enables signaling via G proteins (*green ripples*, step 2) and triggers phosphorylation of the receptor tail (P) by G protein-coupled receptor kinases (GRKs), followed by receptor engagement of b-arrestins (step 3) and endocytosis via clathrin-coated pits (step 4). These events inactivate G protein signaling (*red receptor*) and ensure signal termination from the plasma membrane by endocytic removal of receptors. After receptors arrive in early endosomes, they have the capacity to signal again by engaging G proteins in the endosome membrane (*green ripples*, step 5). Receptors also engage molecular sorting mechanisms in the endosome limiting membrane (not shown), which determine whether internalized receptors are delivered to lysosomes for proteolytic downregulation or are nondestructively recycled to restore surface receptor responsiveness. Many nonpeptide agonist drugs (drug B) are sufficiently membrane-permeant to activate a discrete pool of opioid receptors at the Golgi apparatus and activate receptors from this location (*green ripples*). Some agonists (drug C) induce receptor reorganization in the plasma membrane to change surface signaling (*blue ripples*).

Arrestin-mediated desensitization is an example of *homologous* desensitization, defined as reduced responsiveness of the activated receptor. Homologous desensitization is a negative feedback mechanism that limits the degree of receptor activation. A second type of desensitization is called *heterologous* desensitization, wherein activation of one GPCR alters the responsiveness of a second, different GPCR. Heterologous desensitization often occurs as a result of activation of various kinases, such as protein kinase A (PKA) or protein kinase C (PKC), among others, that are downstream from the first GPCR. These activated kinases can phosphorylate other receptors that contain the proper consensus sequence. Non-GRK-mediated GPCR phosphorylation can also interfere with receptor-transducer-effector coupling and reduce signaling by the phosphorylated receptor. Although activation of non-GRK kinases can mediate heterologous desensitization, these kinases also can participate in negative-feedback, homologous desensitization.

GPCR oligomers. There is substantial evidence to support the existence of functional and dynamic GPCR oligomers, consisting of either GPCR homomers (two or more of the same receptor subtype) or GPCR heteromers (two or more different receptor subtypes). Although GPCR heteromers are well established to occur in heterologous expression systems, evidence for their occurrence in vivo remains somewhat limited. There is also considerable debate over molecular mechanistic issues that underlie the formation of GPCR heteromers, such as whether GPCR heteromer formation is stable or transient (kiss-and-run hypothesis) (Gurevich and Gurevich 2008) and whether ligand binding can induce or stabilize/destabilize heteromer formation (Sierra *et al.* 2020).

The existence of GPCR heteromers greatly increases the number of potential therapeutic targets for the treatment of neuropsychiatric conditions. It has been reported that more than 500 GPCR heteromer pairs have been identified (Borroto-Escuela *et al.* 2014). Notably, GPCR heteromers can have unique signaling, regulatory, and pharmacological

properties and thus are considered by IUPHAR to be distinct receptor entities (Fujita *et al.* 2014). One of the properties of GPCR heteromers that is of great value for pharmacology is interprotomer allosterism. As a result of allosteric interactions between two GPCR protomers of a heteromer, an orthosteric ligand for one of the protomers can act as an allosteric regulator of the affinity, intrinsic efficacy, and/or signaling specificity (i.e., functional selectivity) of an orthosteric ligand for the paired protomer (Figure 2-9). Importantly, these allosteric interactions are ligand-dependent, as is true for all allosteric regulators of GPCRs (Valant *et al.* 2012). Thus, depending on the ligands, an allosteric effect could be facilitatory or inhibitory (antagonistic) or could change cellular signaling specificity for G proteins, b-arrestins, and/or other signaling molecules (Fujita *et al.* 2014; Guitart *et al.* 2014). This ligand dependence increases the opportunities for development of drugs (e.g., bivalent pairs of orthosteric ligands or single ligands with affinity for both protomers) that selectively target heteromers for pharmacotherapy.

(A) The affinity of a ligand for one protomer (*green*) can be altered by the association of the second protomer (*blue*). **(B)** Binding of an orthosteric ligand to one protomer can alter the affinity of an orthosteric ligand for the second protomer. **(C)** Binding of an orthosteric ligand to one protomer can change the signaling efficiency (intrinsic efficacy) of the orthosteric ligand for the second protomer. Shown is efficiency of coupling to a heterotrimeric G protein, but this extends to other signal-transducing molecules (e.g., b-arrestin). **(D)** Binding of an orthosteric ligand to one protomer can alter the efficiency of coupling of the receptor produced by orthosteric ligand binding to the second protomer to each of multiple transducer molecules (i.e., can alter functional selectivity or agonist bias). Shown are alterations in coupling to a G protein versus b-arrestin. **(E)** Orthosteric ligand binding to one protomer can cause a change in the G protein-coupling specificity produced by the orthosteric ligand for the second protomer (this also changes agonist bias). Shown is a change in coupling efficiency to G proteins with two different a subunits (*light vs. dark blue*).

Receptor tyrosine kinases. Receptor tyrosine kinases (RTKs) are transmembrane receptors that possess intrinsic enzymatic activity, i.e., cause phosphorylation, as is the case for all kinases. There are 20 different subfamilies of RTKs. They all possess an N-terminal extracellular domain, a single transmembrane domain, and an intracellular kinase domain followed by a C-terminal tail region. The extracellular domains of the subfamilies are divergent, which allows for some degree of ligand specificity. Ligands for these receptors are growth factors such as ephrins, nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), epidermal growth factor (EGF), transforming growth factor (TGF), and insulin (Trenker and Jura 2020). Ligand activation leads to dimerization of the receptor accompanied by autophosphorylation, as well as the phosphorylation of tyrosine residues on other signaling molecules (Ullrich and Schlessinger 1990). Such phosphorylation triggers intracellular signal transduction cascades, a very important one being increased activity of the guanosine nucleotide-binding protein Ras, which functions as a small GTPase. Activation of Ras then increases the activity of MAPK, which regulates cell functions such as proliferation, differentiation, mitosis, and apoptosis (Du *et al.* 2005; Simon 2000). In addition to signaling through this pathway, RTKs signal through inositol 1,4,5-trisphosphate (IP$_3$), phospholipase C gamma (PLCg), and Janus kinase/signal transducer activator of transcription (JAK/STAT) (Figure 2-10). There is also increasing evidence for biased agonism for RTKs, as has been established for GPCRs (Karl *et al.* 2020). Given the growth-promoting functions of RTKs, it is not surprising that dysfunction of Ras/MAPK signaling is strongly implicated in the development of many cancers. Such dysfunction has also been implicated in diabetes, severe bone disorders, and arteriosclerosis (Lemmon and Schlessinger 2010; Simon 2000). Changes in RTK signaling have also been hypothesized to be involved in neurological and/or psychiatric disorders (Autry and Monteggia 2012; Duman and Monteggia 2006; Gupta *et al.* 2013; Hashimoto *et al.* 2004).

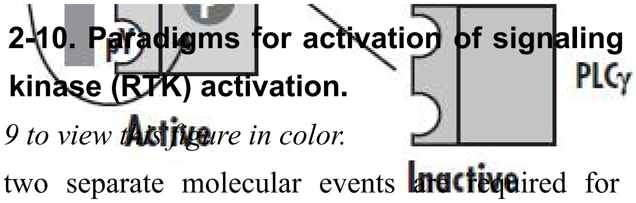

FIGURE 2-10. Paradigms for activation of signaling proteins in response to receptor tyrosine kinase (RTK) activation.

See Plate 9 to view this figure in color.

At least two separate molecular events are required for RTK-induced activation of signaling molecules. Given that many protein targets of RTKs are located at the cell membrane, translocation of RTK to the cell membrane is essential for activation of many effector proteins. **(A) Activation of PKB (also known as Akt) by membrane translocation.** PtdIns(3,4,5)P3 generated in response to growth factor stimulation serves as a binding site for the PH domains of PDK1 and PKB. Membrane translocation is accompanied by release of an autoinhibition leading to activation of PDK1 and PKB kinase activities. Full activation of PKB requires phosphorylation by PDK1 (and also by PDK2). Activated PKB phosphorylates a variety of target proteins that prevent apoptotic death and regulate various metabolic processes. **(B) Activation by a conformational change.** Binding of the SH2 domains of p85, the regulatory subunit of PI-3 kinase, to pTyr sites on activated receptors releases an autoinhibitory constraint that stimulates the catalytic domain (p110). PI-3 kinase catalyzes the phosphorylation of the 39 positions of the inositol ring of PtdIns(4)P and PtdIns(4,5)P2 to generate PtdIns(3,4)P2 and PtdIns(3,4,5)P3, respectively. **(C) Activation by tyrosine phosphorylation.** Binding of the SH2 domains of PLCg to pTyr sites in activated receptors facilitates tyrosine phosphorylation of PLCg as well as membrane translocation, a process mediated in part by binding of the PH domain to PI-3 kinase products. Tyrosine phosphorylation is essential for PLCg activation, leading to hydrolysis of PtdIns(4,5)P2 and generation of the two second messengers Ins(1,4,5)P3 and diacyglycosol. In the developing brain, RTKs promote neuronal differentiation and axon targeting; however, in the adult brain, RTKs regulate structural and synaptic plasticity (Chao 2003). Consequently, RTKs are thought to play a role in learning and memory. In particular, BDNF may serve as a mediator rather than a modulator of synaptic plasticity and communication (Johnstone and Mobley 2020; Park and Poo 2013). Interfering with BDNF signaling, possibly by targeting its receptor, TrkB, is a developing strategy for treatments for neurological or psychiatric disorders, including alcohol use disorder (Autry and Monteggia 2012; Gupta *et al.* 2013; Hamada and Lasek 2020; Nagahara and Tuszynski 2011). The involvement of BDNF/TrkB signaling in the antidepressant effect of ketamine (Carreno *et al.* 2020; Duman and Monteggia 2006; Kavalali and Monteggia 2020; Yang *et al.* 2019) gives further credence to a role for RTKs in the mechanism of action of psychotherapeutic drugs. Of course, the widespread growth and synaptic effects of BDNF raise important caveats for therapies targeting BDNF signaling.

Neurotransmitter and Neuropeptide Systems

Serotonergic System

Serotonin was first synthesized by Maurice Rapport in 1948 after he identified it as a vasoconstrictor substance in blood (Rapport *et al.* 1948). Later, it was found that serotonin was the same molecule, previously called enteramine, isolated from chromaffin cells of the intestinal muscosa by Erspamer (1937) in 1935. Most of the serotonin in the body is found outside the CNS, in enterochromaffin cells of the gastrointestinal system (90%) and in platelets (8%) (Gershon 2013). Although 5-HT plays a vital role in the regulation of a wide variety of CNS functions, only about 1%-2% of serotonin is found in the CNS. Serotonin is an indolealkyl amine (see Figure 2-1). Even though serotonergic cells represent only a small percentage of neurons in the brain (~0.0001%), serotonergic neurons have an enormous influence on other neurons in brain. It has been estimated that each cortical target neuron receives approximately 200 contacts by serotonergic neurons (Jacobs and Azmitia 1992). Because of serotonin's key role in the regulation of mood and affective states, finding ways to modify and stabilize serotonin neuron activity and function has been a major ongoing focus of psychiatric disorder research and pharmacotherapy.

An excess of serotonin receptor activation, produced by high dosages or combinations of certain drugs--such as selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), cocaine, and various serotonergic agonists (buspirone, triptans, L-tryptophan, amphetamine derivatives, 3,4-methylenedioxymethamphetamine [MDMA, "Ecstasy"])--can cause a variety of effects collectively known as the *serotonin syndrome* (Simon and Keenaghan 2021). In humans, symptoms of serotonin syndrome (which can be life-threatening) include altered mental status, autonomic dysfunction (hyperthermia, high blood pressure, tachycardia, pupil dilation), and neuromuscular excitation (e.g., tremor, hypertonia, hyperreflexia). A serotonin syndrome can also occur in animals, characterized by tremor, ataxia, loss of plantar reflex, gastrointestinal effects, pupil dilatation, piloerection, and increased motor activity (Haberzettl *et al.* 2013). In rats and mice, the characteristic behaviors observed include forepaw treading, resting tremor, rigidity, Straub tail, hind limb abduction, and head weaving.

5-HT neurons project widely throughout the CNS and innervate virtually every part of the neuroaxis (Figure 2-11A). Serotonin is synthesized from the essential amino acid L-tryptophan. L-tryptophan undergoes hydroxylation at the 5-position of the ring by a rate-limiting enzyme, tryptophan hydroxylase, to form 5-hydroxytryptophan (5-HTP). 5-HTP is converted to 5-HT by the enzyme aromatic L-amino acid decarboxylase (AADC). In neurons, 5-HT is stored at high concentrations in vesicles by the action of a vesicular monoamine transporter (VMAT), which is discussed in more detail below. Upon activation of raphe serotonergic neurons, depolarization of the neuron terminals by invasion of action potentials promotes fusion of serotonin-containing vesicles to the membrane and extracellular release of serotonin (Figure 2-11B). In addition to being released at the synapse, serotonin can be released extrasynaptically from cell bodies, dendrites, and axons (Quentin *et al.* 2018). This type of extrasynaptic release, termed *volume transmission*, has slow kinetics and influences a larger area than that influenced by synaptic release. The impact of these two modes of neurotransmission on pathophysiological functions, behaviors, and pharmacotherapy is not yet clear.

(A) Location of the major serotonin (5-hydroxytryptamine [5-HT])-producing cells (raphe nuclei) innervating brain structures. **(B)** Various cellular regulatory processes involved in serotonergic neurotransmission and sites of action of drugs affecting serotonergic transmission. *L-Tryptophan*, the precursor for 5-HT, is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TrpH). Aromatic L-amino acid decarboxylase (*AADC*) then converts 5-HTP to 5-HT. Once released from the presynaptic terminal, 5-HT can interact with a variety (14 different types) of presynaptic and postsynaptic receptors. *Sumatriptan*, a 5-$HT_{1B,1D}$ receptor agonist, has antimigraine effects that are thought to be due to activation of $HT_{1B,1D}$ receptors expressed on smooth muscle (to produce vasoconstriction) and also on pain-sensing neurons (i.e., *nociceptors*) (to reduce the release of pain-related neuropeptides). *Buspirone* is a partial 5-HT_{1A} receptor agonist that activates both pre-and postsynaptic receptors. *Cisapride* is a preferential 5-HT_4 receptor agonist that is used to treat irritable bowel syndrome as well as nausea associated with antidepressants. Binding of 5-HT to G protein-coupled receptors (GPCRs) that are coupled to adenylyl cyclase (AC) and phospholipase C beta (PLCb) will result in production of a cascade of second-messenger and cellular effects. Lysergic acid diethylamide (*LSD*) likely interacts with numerous 5-HT receptors to mediate its effects. Pharmacologically, this ligand is often used as a 5-HT_2 receptor agonist in receptor-binding experiments. *Ondansetron* is a 5-HT_3 receptor antagonist that is marketed as an antiemetic agent for chemotherapy patients but is also given to counteract side effects produced by antidepressants in some patients. 5-HT has its action terminated by being taken back into the presynaptic neuron through 5-HT transporters (5-HTTs [also called SERTs]). (Note that 5-HTTs are located extrasynaptically, not synaptically [as depicted in figure].) Once inside the neuron, 5-HT can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. The selective serotonin reuptake inhibitors (*SSRIs*) and older-generation tricyclic antidepressants (*TCAs*) are able to interfere with or block the reuptake of 5-HT. 5-HT is metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO), located on the outer membrane of mitochondria or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). *Reserpine* causes a depletion of 5-HT in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). *Tranylcypromine* is an MAO inhibitor (MAOI) and an effective antidepressant. *Fenfluramine* (an anorectic agent) and 3,4-methylenedioxymethamphetamine (*MDMA*; "Ecstasy") are able to facilitate 5-HT release by altering SERT function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP_3 = inositol 1,4,5-triphosphate.

Once released, serotonin can act on receptors (discussed below) located on postsynaptic cells (heteroreceptors) and on the serotonergic neurons themselves (presynaptic receptors, autoreceptors). Autoreceptors on serotonergic neurons can be found on cell bodies (somatodendritic autoreceptors) and on neuron terminals (terminal autoreceptors). Serotonergic somatodendritic autoreceptors are composed of the 5-HT$_{1A}$ subtype (which also can be found on postsynaptic neurons) and function to decrease the firing rate of the serotonergic neurons. Autoreceptors on the serotonin neuron terminals are of the 5-HT$_{1B}$ subtype (which also can be found on postsynaptic neurons) and function to decrease the release of serotonin from the activated neuron. In these ways (i.e., via reduced cell firing and reduced serotonin release), serotonergic autoreceptors mediate negative feedback to regulate the activity of serotonergic neurons.

Serotonin's actions are terminated by rapid uptake back into serotonergic neurons, a process mediated by serotonin transporters (see "Serotonin Transporters" below). Once back inside the cell, serotonin can be repackaged into vesicles (via VMAT2) or enzymatically degraded by monoamine oxidase (MAO), located on the outer membrane of mitochondria, to 5-hydroxyindoleacetic acid (5-HIAA). 5-HIAA levels in cerebrospinal fluid provide an index of serotonin levels in the CNS, whereas 5-HIAA levels in urine provide an index of peripheral serotonin levels and are diagnostic for the presence of carcinoid tumors of enterochromaffin cells.

The importance of serotonin in the CNS has been demonstrated through use of pharmacological tools. Destruction of serotonergic neurons with neurotoxins (e.g., *para*-chloroamphetamine [pCA] or 5,7-dihydroxytryptamine [5,7-DHT]) or with electrolytic lesions of the raphe nuclei, or depletion of serotonin with inhibitors of synthesis (e.g., *para*-chlorophenylalanine [pCPA]) or inhibitors of VMAT (e.g., reserpine) produces a variety of behavioral changes in animals (e.g., nonaggression, hypersexuality, hyperlocomotion). Dietary restriction of the essential amino acid tryptophan in humans can cause a resurgence of depressive symptoms in patients treated successfully with SSRIs (see below) (Salomon *et al.*

1993). Conversely, inhibition of serotonin metabolism via inhibition of MAO can lead to improved mood--and in fact, MAOIs are antidepressant drugs (Culpepper 2012).

Serotonin Receptors

Serotonin acts on a large variety of receptors in the CNS to regulate numerous physiological functions and behaviors. The history of serotonin receptor nomenclature is quite complex (for an excellent review, see Barnes *et al.* 2021) starting in 1957 with the identification of two serotonin receptor subtypes by Gaddum and Picarelli (1957). There are 14 receptor subtypes distributed into seven families. With the exception of 5-HT_3 receptors, which are ligand-gated ion channels, all of the serotonin receptors are GPCRs (Table 2-2).

The serotonin type 1 receptor subfamily consists of 5-HT$_{1A}$, 5-HT$_{1B}$, 5-HT$_{1D}$, 5-HT$_{1e}$, and 5-HT$_{1F}$ subtypes, which share 40%-60% of their sequence identity. These receptors are best known to couple to the G$_{i/o}$ family of G proteins (although not exclusively), leading to inhibition of adenylyl cyclase activity, activation of G protein-coupled inwardly rectifying potassium (GIRK) channels, and inhibition of calcium channels in neurons. Although originally defined as a member of the 5-HT$_1$ subfamily, the 5-HT$_{1C}$ receptor was later recharacterized as the 5-HT$_{2C}$ receptor on the basis of its structural and functional similarity to the 5-HT$_2$ subfamily.

5-HT_{1A} receptors are distributed widely throughout the CNS, notably in limbic regions, consistent with these receptors' prominent role in neuropsychiatric disease, including major depressive disorder, anxiety disorders, and schizophrenia (Celada *et al.* 2013). A role for 5-HT_{1A} receptors has been indicated in a variety of other conditions, such as cognitive impairment, pain, fear, substance use disorders, Parkinson's disease, female sexual dysfunction, and respiratory dysfunction. Although a variety of clinically used drugs are known to directly target 5-HT_{1A} receptors (e.g., buspirone, clozapine, ziprasidone, aripiprazole, vilazodone), there are no FDA-approved drugs that selectively target the 5-HT_{1A} receptor. Additionally, the 5-HT_{1A} receptor is involved in the mechanism of antidepressant action of a variety of drugs (Richardson-Jones *et al.* 2010; Samuels *et al.* 2016) that act to increase serotonin levels, including SSRIs, MAOIs, and tricyclic antidepressants (TCAs), although it should be noted that many receptors have been found to play a role in the action of these drug classes. Development

of selective ligands that target the 5-HT_{1A} receptor will likely be of value in the treatment of mood disorders.

In addition to being postsynaptic receptors, 5-HT_{1A} receptors are also located on the soma and dendrites of serotonergic neurons in the raphe nuclei (somatodendritic autoreceptors). These receptors participate in negative-feedback regulation of serotonergic neurons, as their activation by serotonin released by activated serotonergic neurons inhibits the firing of serotonergic neurons, resulting in decreased serotonin release. Desensitization of these somatodendritic autoreceptors has been found to play a role in the mechanism of action of SSRIs (Artigas *et al.* 2006; Millan 2006), and

small interfering RNA (siRNA)-induced knockdown of 5-HT_{1A} receptors produces robust antidepressant-like effects in mice. By contrast, activation of 5-HT_{1A} autoreceptors produces anxiolytic behaviors in rodents (De Vry *et al.* 2004).

As is the case for 5-HT_{1A} receptors, 5-HT_{1B} receptors are expressed both postsynaptically and presynaptically on serotonergic neurons. However, 5-HT_{1B} autoreceptors are expressed on terminals of serotonergic neurons located in various target areas throughout the CNS. Activation of terminal 5-HT_{1B} receptors reduces release of serotonin from activated neurons, thereby participating in negative-feedback regulation of serotonin release. The 5-HT_{1B} receptor plays a role in depression and anxiety behaviors as well as in aggression and impulsivity. Whereas presynaptic 5-HT_{1B} autoreceptors appear to be involved in depression and anxiety in mice (Nautiyal *et al.* 2016), postsynaptic 5-HT_{1B} receptors regulate aggressive behavior and impulse control (Nautiyal *et al.* 2015). However, studies of the function of 5-HT_{1B} receptors have been complicated by both pharmacological differences across species and similarity to the 5-HT_{1D} receptor, although the expression level of the 5-HT_{1B} receptor is much higher than that of the 5-HT_{1D} receptor. With a lack of selective ligands, identification of distinct functional roles of these two receptor subtypes remains a challenge. For a discussion of the rather confusing history of the nomenclature regarding the 5-HT_{1B} and 5-HT_{1D} receptors, see the excellent review by Barnes *et al.* (2021). Currently, there are no drugs available that can selectively target pre-versus postsynaptic 5-HT_{1B} receptors.

5-HT_{1B} receptors, along with 5-HT_{1D} and 5-HT_{1F} receptors, are targets for the triptan class of drugs (e.g., sumatriptan, zolmitriptan, naratriptan, rizatriptan) that are used to treat migraine. Initially, the antimigraine efficacy of the triptans was attributed to agonist action at the 5-HT_{1B} receptor to promote vasoconstriction in arteries in the brain (Goadsby *et al.* 2017). However, the 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors are also located on sensory neurons that mediate pain neurotransmission. Activation of these receptors inhibits pain-sensing neuron (nociceptor) release of the neuropeptide calcitonin gene-related peptide (CGRP), thereby reducing pain neurotransmission. Thus, inhibition of pain-sensing neurons that innervate the meninges of the CNS by activation of 5-HT_{1B}, 5-HT_{1D}, and/or

5-HT_{1F} receptors is thought to be the primary therapeutic mechanism of the triptans (Goadsby *et al.* 2017). Notably, agonists selective for the 5-HT_{1F} receptor have been developed that are effective in the acute treatment of migraine pain. In 2019, the 5-HT_{1F} agonist lasmiditan was approved for use in the treatment of migraine (Kuca *et al.* 2018).

The 5-HT_2 family consists of three members, 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}. The 5-HT_{2A} and 5-HT_{2C} receptors share significant sequence homology, making the development of selective ligands difficult. Many antagonists initially developed for the 5-HT_{2A} receptor are now known to bind to the 5-HT_{2C} receptor. The canonical signaling pathway for all three of these receptors is the $G_{q/11}$ family of G proteins, which activates phospholipase C to produce two second messengers derived from hydrolysis of inositol 4,5-bisphosphate: 1) diacylglycerol, which activates protein kinase C (PKC), and 2) inositol 1,4,5-trisphosphate (IP_3), which mobilizes intracellular calcium from the endoplasmic reticulum. Activation of these signaling pathways influences a great many cellular processes and is generally excitatory in neurons, in contrast to the inhibitory actions of the 5-HT_1 receptors. However, as is the case for all GPCRs, signaling by 5-HT_2 receptors is not restricted to the most studied, canonical signaling pathway. Coupling of 5-HT_2 receptors to multiple G proteins (such as G_i) as well as

to G protein-independent pathways has been demonstrated (for a review, see Barnes *et al.* 2021).

The 5-HT_{2A} receptor can be found both in the CNS and in the periphery. It is especially prominent in vascular smooth muscle, where it is involved in regulation of the contractile state. In the CNS, 5-HT_{2A} receptors are widely distributed but are found especially in cortical and limbic areas.

The 5-HT_{2A} receptor is perhaps best known as a central target for hallucinogenic drugs, such as lysergic acid diethylamide (LSD), *N,N*-dimethyltryptamine (DMT), and psilocybin (Nichols 2016). Although there was evidence from studies before 1970 that serotonergic hallucinogens were markedly effective in treating various neuropsychiatric conditions (e.g., obsessive-compulsive disorder [OCD], substance use disorders [alcohol, nicotine, opioid], anxiety, depression), clinical research of these substances was curtailed when LSD was placed in Schedule I of the 1970 Controlled Substances Act, largely because of its popularity as a recreational drug. Fortunately, research has resumed, and there is now evidence that acute exposure to these classical psychedelic drugs, under controlled, supportive environmental conditions, is highly effective in treating depression (in cancer patients, in individuals with treatment-resistant depression, and in persons with substance use disorders (Johnson *et al.* 2019). The FDA granted "breakthrough therapy" status to psilocybin in 2018 for use in clinical trials for treatment-resistant depression (Carhart-Harris *et al.* 2021) and in 2019 for use in clinical trials for major depressive disorder (Davis *et al.* 2021).

The 5-HT_{2A} receptor is also an important target for atypical antipsychotics in the treatment of schizophrenia (Kantrowitz 2020). The first-generation (also known as "conventional") antipsychotics were largely dopamine D_2 receptor antagonists (e.g., haloperidol), and although they were effective in diminishing psychosis, they were associated with serious adverse extrapyramidal side effects (EPS). The second-generation (also known as "atypical") antipsychotics (e.g., clozapine, risperidone, olanzapine, paliperidone, lumateperone) have reduced affinity for dopamine D_2 receptors, greater 5-HT_{2A} receptor antagonism, and lower risk of EPS, albeit with increased liability for weight gain and metabolic syndrome. Although the 5-HT_{2A} receptor plays a central role in the reduced adverse EPS of the atypical antipsychotics, it does not appear to be essential for efficacy in treatment of psychotic symptoms. It should be noted that in addition to dopamine D_2 and 5-HT_{2A} receptors, atypical antipsychotics have affinity for a variety of receptor subtypes (e.g., the 5-HT_{2C} receptor), which may be important in their mechanism of action (Meltzer 2017). Given the multifaceted complexity of neuropsychiatric disorders such as schizophrenia, it should not be surprising that an effective treatment strategy may require targeting multiple receptor systems with nonselective drugs (i.e., a "magic shotgun" versus a "magic bullet" approach [Roth *et al.* 2004]).

Although 5-HT$_{2A}$ antagonism does not appear to play a substantive role in the mechanism of action of atypical antipsychotics, the 5-HT$_{2A}$ antagonist pimavanserin was approved by the FDA in 2016 for treatment of psychosis associated with Parkinson's disease. The purported mechanism of pimavanserin's antipsychotic efficacy is 5-HT$_{2A}$ receptor inverse agonism (i.e., reduction of constitutive receptor activity). Pimavanserin also has inverse agonist efficacy at the 5-HT$_{2C}$ receptor; however, it does not have appreciable affinity at dopaminergic receptors. Whether the difference in antipsychotic efficacy of pimavanserin versus that of the atypical antipsychotics is due to inverse agonism versus antagonism is not clear (Nutt *et al.* 2017). Furthermore, pimavanserin's inverse agonism has been demonstrated only in vitro, in heterologous expression systems. Caution must be exercised in extrapolating in vitro effects to in vivo mechanisms of action, given that constitutive receptor activity and inverse agonism are dependent on cell phenotype and physiological state (Berg and Clarke 2018).

The 5-HT$_{2B}$ receptor was first identified in the fundus of the rat stomach and in the periphery and is involved in regulation of gastrointestinal, cardiac, vascular, and pulmonary functions. There have been relatively few studies of this receptor's role in the CNS. Although there are currently no clinically available drugs that selectively target the 5-HT$_{2B}$ receptor, a strong case for development of compounds that target the 5-HT$_{2B}$ receptor has been made on the basis of studies demonstrating 5-HT$_{2B}$ receptor-mediated regulation of serotonergic and dopaminergic neuronal activity (Devroye *et al.* 2018). However, in view of reports that drugs with agonism at 5-HT$_{2B}$ receptors can produce lethal cardiac valvulopathies and pulmonary hypertension (an effect that caused drugs such as fenfluramine, pergolide, and cabergoline to be withdrawn from the market), development of 5-HT$_{2B}$-targeting drugs must proceed with caution.

Although the 5-HT$_{2C}$ receptor is expressed throughout the brain, its expression level is much lower than that of the 5-HT$_{2A}$ receptor, except in the choroid plexus. The messenger RNA (mRNA) for the 5-HT$_{2C}$ receptor is the only GPCR found to date that undergoes a posttranscriptional process called mRNA editing, which changes the amino acid sequence of three amino acids in the second intracellular loop. As a result of this change in sequence, there are 14 different isoforms of the 5-HT$_{2C}$ receptor that can be expressed in humans. Changes to the amino acid sequence in the second intracellular loop due to mRNA editing result in changes in the receptor's ability to couple to G proteins and can also change the receptor's signaling specificity. mRNA editing is a regulated phenomenon in cells; thus, the pattern of 5-HT$_{2C}$ receptor isoform expression--and subsequently 5-HT$_{2C}$ receptor function--is subject to change with cell phenotype and physiological state. While it is clear that 5-HT$_{2C}$ mRNA editing markedly alters 5-HT$_{2C}$ receptor function (Olaghere da Silva *et al.* 2010), the consequences of these changes for pathophysiology and therapeutics are currently unknown.

Consistent with this receptor's wide distribution in the brain, activation of the 5-HT$_{2C}$ receptor leads to a variety of behavioral responses in rodents, including anxiety, hypolocomotion, hyperthermia, hypophagia, and penile erection. Importantly for therapeutics, the 5-HT$_{2C}$ receptor has been shown to regulate compulsive drug-and food-seeking behaviors, energy homeostasis, mood and cognition disorders, and seizures (Di Giovanni and De Deurwaerdere 2016), suggesting that 5-HT$_{2C}$ ligands may be effective in treating substance-related and addictive disorders (Collins *et al.* 2018) as well as other neuropsychiatric conditions (Palacios *et al.* 2017).

Many reports have shown that selective 5-HT$_{2C}$ agonists reduce food intake, which led to optimism that a compound to prevent obesity could be developed (Higgins *et al.* 2020). Lorcaserin, a selective 5-HT$_{2C}$ agonist, was approved by the FDA in 2012 for the management of body weight. Lorcaserin's anorexigenic action is mediated by its ability to increase levels of proopiomelanocortin in the hypothalamus. Unfortunately, the efficacy of lorcaserin in promoting weight loss was modest. Moreover, due to an increased incidence of cancer in patients treated with lorcaserin, it was removed from the market in 2020.

5-HT_3 receptors are ligand-gated cation channels composed of five subunits that are expressed in a variety of brain regions but notably are present at high densities in the dorsal vagal complex of the brain stem (area postrema and nucleus tractus solitarius). This area is involved in the vomiting reflex, and 5-HT_3 antagonists (e.g., ondansetron, granisetron, palonosetron) are strong antiemetics and are frequently used to treat emesis experienced after surgery or related to cancer chemotherapy (Kovac 2016; Navari 2013). There are many potential 5-HT_3 receptor isoforms based on various combinations of the five subunits and through alternative mRNA splicing. Although there are currently no clinically available drugs that target the 5-HT_3 receptor for conditions other than emesis, ongoing preclinical studies are investigating the role of the 5-HT_3 receptor in anxiety, cognition, pain, and learning and memory (Fakhfouri *et al.* 2019). For example, in addition to its antidepressant activity, the SSRI vortioxetine may enhance cognition by antagonism of 5-HT_3 receptors (Riga *et al.* 2016).

Compared with the extensive work on 5-HT_1 and 5-HT_2 receptors, much less is known about the role of $5\text{-HT}_{4\text{-}7}$ receptors in neuropsychiatric disorders. The canonical signaling pathway for 5-HT_4, 5-HT_6, and 5-HT_7 receptors is through the G_s family of G proteins (stimulation of adenylyl cyclase activity), whereas the 5-HT_5 receptor couples predominantly to $G_{i/o}$ (inhibition of adenylyl cyclase) but can signal via a variety of different cascades (Noda *et al.* 2004). Preclinical studies suggest a role for 5-HT_4 receptors in cognition, mood (anxiety and depression), and feeding behavior (Bureau *et al.* 2010). Unfortunately, clinical studies have not been done, perhaps due to concerns about adverse effects associated with the cardiac and gastrointestinal actions of 5-HT_4 agonists (see Barnes *et al.* 2021). There are very few studies of behavioral effects mediated by 5-HT_5 receptors, perhaps due to the lack of selective ligands. Several studies have demonstrated a role for 5-HT_6 receptor antagonism in cognition, consistent with this receptor's localization in cortical neurons. These findings paved the way for clinical trials of 5-HT_6 antagonists, in conjunction with cholinesterase inhibitors, for treatment of Alzheimer's disease (Hung and Fu 2017). Although early findings appeared promising, subsequent studies failed to find a significant effect from two 5-HT_6 antagonists, idalopirdine and intepirdine, in improving cognition (Khoury *et al.* 2018). Paradoxically, it appears that 5-HT_6 agonists may have procognitive effects (Meneses *et al.* 2011). In preclinical studies, the 5-HT_7 receptor has been linked to circadian rhythm regulation, temperature, cognition, mood, pain, substance use disorders, and seizures (Blattner *et al.* 2019; Okubo *et al.* 2021). Although there are no selective 5-HT_7 ligands in clinical use, many drugs, including antidepressants and antipsychotics, have an affinity for 5-HT_7 receptors; however, the contribution of this receptor to these drugs' therapeutic efficacy or adverse-effect profile is not known. In 2018, a 5-HT_7 antagonist, JNJ-18038683, entered clinical testing for the treatment of cognitive impairment associated with bipolar disorder; as of June 2023, this trial is ongoing (ClinicalTrials.gov 2021).

Serotonin Transporters

The serotonin (5-HT) transporter (SERT [also called 5-HTT]) is the primary mechanism terminating serotonergic signaling. Located extrasynaptically on presynaptic serotonergic nerve terminals, SERT is responsible for high-affinity uptake of serotonin from extracellular fluid into the terminal, where serotonin is then either broken down enzymatically by MAO or repackaged into vesicles via the vesicular monoamine transporter 2 (VMAT2) (for a review, see German *et al.* 2015). SERT and other

biogenic amine transporters were originally thought to reside in the synaptic cleft, but electron microscopy studies have since revealed these transporters to reside extrasynaptically, predominantly on axons and axon terminals (e.g., Pickel and Chan 1999). The important implication from these findings is that serotonin neurotransmission can operate via paracrine (volume) transmission (see Fuxe *et al.* 2007; Borroto-Escuela *et al.* 2021). SERT is also found on nonserotonergic dendrites and glia, although it is more sparsely expressed on these cell types (Pickel and Chan 1999). SERT is found at its highest density in serotonin cell bodies in the dorsal and median raphe nuclei. It is broadly located in terminal regions, including limbic brain structures important in the regulation of mood and arousal states, such as hippocampus, amygdala, and entorhinal cortex (Hensler *et al.* 1994). First cloned in 1991 (Blakely *et al.* 1991; Hoffman *et al.* 1991), SERT is a member of the solute carrier 6 (SLC6) family and is encoded by the gene *SLC6A4*. It has 12 transmembrane-spanning domains, intracellular N-and C-termini, a large extracellular loop with glycosylation sites, and intra-and extracellular loops containing phosphorylation sites. (For comprehensive reviews of SERT structure, function, and regulation, see Kristensen *et al.* 2011, Pramod *et al.* 2013, and Ramamoorthy *et al.* 2011.)

SERT is a symporter (i.e., a membrane protein involved in the transport of two different molecules across the cell membrane in the same direction), deriving energy for transport of serotonin molecules through its co-transport with sodium ions into the nerve terminal. High sodium concentrations are maintained outside the neuron by the plasma membrane sodium/potassium ATPase pump. Serotonin, and other biogenic amines, use the electrochemical gradient created by high sodium levels outside the cell to gain entry. Thus, serotonin transport is not directly energy requiring. SERT itself is a dynamic protein. It can form oligomers (Jayaraman *et al.* 2021; Sitte *et al.* 2004) and is tightly regulated by many kinases, phosphatases, and auto-and heteroreceptors (Bermingham and Blakely 2016; Steiner *et al.* 2008). SERT is trafficked in and out of the plasma membrane and exists in both "on" and "off" states when in the plasma membrane. Psychostimulants and antidepressants that interact with SERT also regulate its trafficking and/or its activation state in a manner dependent on whether the drug is a transported substrate (e.g., MDMA) or a blocker (e.g., fluoxetine) (Ramamoorthy and Blakely 1999).

Dysfunction in serotonergic neurotransmission has long been linked to many psychiatric disorders, including depressive disorders, anxiety disorders, OCD, and autism spectrum disorder. Because serotonin is critical for normal brain development, abnormalities in serotonin neurotransmission during embryonic and postnatal development have been the focus of intense research. Genetic or pharmacological perturbations of SERT during development have been tied to autism spectrum disorder, as well as to increased anxiety and exaggerated stress response (Daws and Gould 2011). Not surprisingly, SERT, as a major regulator of the strength and duration of serotonin signaling, has been a primary target for development of therapeutics to treat these disorders. SSRIs, which act through blockade of SERT, are the most commonly prescribed pharmaceutical treatment for these psychiatric disorders, although evidence on their efficacy and tolerability is mixed (Cipriani *et al.* 2018). SSRIs include citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline.

In general, the majority of patients treated with SSRIs do not receive full symptom relief, bringing into question the therapeutic utility of increasing extracellular serotonin. However, it is now broadly accepted that transporters for biogenic amines are

promiscuous (i.e., capable of taking up biogenic amines other than their "native" neurotransmitter). For example, the norepinephrine and dopamine transporters (NET and DAT) are capable of serotonin uptake, and there is evidence that drugs that block SERT, NET, and DAT are therapeutically more efficacious than drugs that selectively block only one of these transporters (see Daws 2009; Sharma *et al.* 2015). In addition, there is rapidly growing evidence that organic cation transporters (OCTs) and the plasma membrane monoamine transporter (PMAT) play an important role in biogenic amine homeostasis in the brain (Daws 2021; Koepsell 2020). OCTs and PMAT have low affinity for serotonin transport but a high capacity to transport serotonin, meaning that when extracellular serotonin increases, as is expected following treatment with an SSRI, these so-called uptake-2 transporters for serotonin are able to efficiently clear serotonin from the extracellular fluid. In doing so, they effectively "keep a brake on" the ability of SSRIs to increase extracellular serotonin, which is thought to be required to trigger downstream events that lead to maximum therapeutic benefit. Because OCTs and PMAT are polyspecific organic cation transporters, their activity might also help account for poor treatment response to antidepressants that block NET (e.g., reboxetine) or DAT (e.g., bupropion) as well. The role of OCTs and PMAT in the treatment of psychiatric disorders is an area of active research.

Numerous gene variants of SERT have been identified (for reviews, see Kristensen *et al.* 2011 and Murphy and Lesch 2008). Among the most common gene variants is the serotonin transporter-linked polymorphic region (5-HTTLPR) polymorphism. Individuals who carry this variant have a variable number of tandem repeats (44 base pair insertion/deletion) in the SERT promotor region. Individuals who carry the short (s) variant have reduced expression of the SERT protein relative to individuals homozygous for the long (l) allele. Notably, the 5-HTTLPR polymorphism has been linked with numerous psychiatric disorders, including depression and anxiety-related disorders as well as alcohol use disorder (Caspi *et al.* 2003, 2010; Kristensen *et al.* 2011; Murphy and Lesch 2008). Worth noting is the finding that mouse models of this SERT gene variant, which have reduced SERT expression, have fivefold higher extracellular concentrations of serotonin than their wild-type counterparts (Mathews *et al.* 2004), bringing into question the dogma that low extracellular serotonin is linked to psychiatric disorders. Moreover, individuals carrying this polymorphism are reported to be less responsive to treatment with SSRIs (Serretti *et al.* 2007). In murine studies, the finding that a mouse model of this human gene variant displays increased expression of organic cation transporter type 3 (OCT3), presumably to compensate for the constitutive reduction in SERT (Baganz *et al.* 2008), raises the possibility that the activity of OCT3 may account for the poor therapeutic response to SSRIs in these individuals. It is known that long-term treatment with SSRIs downregulates SERT function and expression, and this downregulation is thought to contribute to the delay of weeks to months in the onset of therapeutic efficacy (e.g., Benmansour *et al.* 1999). Future studies examining potential compensation in "uptake-2" transporters may help provide mechanistic insights into why the benefits of SSRIs tend to wane after prolonged treatment in some individuals. Rare, nonsynonymous SERT gene variants have been linked to OCD and autism spectrum disorder. Notably, these SERT gene variants display a gain-of-function phenotype, which appears to be due to increased intrinsic SERT activity and/or increased expression in the plasma membrane (Veenstra-Vanderweele *et al.* 2012).

SERT is a prime regulator of serotonergic neurotransmission. What is clear from the literature is that genetic perturbations in SERT function that lead to either decreases or increases in extracellular serotonin are associated with a number of psychiatric disorders. SERT and its many regulators, as well as other transporters for serotonin, will continue to be a focus of research aimed at improving on current treatments for these disorders.

(A) Dopaminergic neurons are located in the ventral midbrain in the A9 (substantia nigra pars compacta) and A10 (ventral tegmental area) regions. DA = dopamine.**(B)** Synthesis of dopamine starts with the nonessential amino acid L-tyrosine. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) then converts L-DOPA to dopamine, which can be metabolized to 3,4-dihydroxyphenylacetic acid (DOPAC) by intraneuronal monoamine oxidase (MAO) or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Once released, dopamine acts on pre-and postsynaptic metabotropic receptors and is terminated via reuptake by perisomatic dopamine transporters (DATs). (Note that DATs are located extrasynaptically, not synaptically [as depicted in figure].) AMPT = a-methyl-*p*-tyrosine; cAMP = cyclic adenosine monophosphate; COMT = catechol-O-methyltransferase; HVA = homovanillic acid; MT = methoxytyramine. **(C)** Four separate dopamine pathways are present in the brain that play distinct roles in pathophysiology and therapeutic intervention: the mesocortical pathway (*yellow*), the nigrostriatal pathway (*blue*), the mesolimbic pathway (*red*), and the tuberoinfundibular pathway (*green*).

Dopaminergic System

An elegant biosynthetic pathway exists in the brain for catecholamine neurotransmitters. These neurotransmitters consist of a single amine group and a catechol nucleus (a benzene ring with two hydroxyl groups) (see Figure 2-1), and a single pathway is used in the generation of three distinct neurotransmitters: dopamine, norepinephrine, and epinephrine. This metabolic pathway (tyrosine - L-DOPA - dopamine - norepinephrine - epinephrine) is capable of generating one of these three neurotransmitters based solely on the enzymes expressed by a particular neuron. In the case of dopaminergic neurons, the enzymes tyrosine hydroxylase and aromatic L-amino acid decarboxylase (AADC; also known as DOPA decarboxylase) are highly expressed, whereas the enzymes responsible for subsequent metabolism of dopamine to norepinephrine are not present in appreciable quantities. This metabolic pathway is highly relevant for treatment of Parkinson's disease, a debilitating neurodegenerative disorder resulting in loss of dopamine neurons in the brain. Although there is no cure for this disease, a number of treatments are available that can control motor symptoms. These drugs typically mimic the effects of dopamine or increase the levels of dopamine in the brain. Interestingly, dopamine itself cannot be used to treat this disease because it is too polar to cross the blood-brain barrier and enter the CNS. Instead, the biological precursor for dopamine, L-dihydroxyphenylalanine (also known as levodopa or L-DOPA), is used because it can utilize an amino acid transporter system to enter the brain. L-DOPA is often administered in tandem with a peripherally acting AADC inhibitor to minimize peripheral side effects and to increase the amount of L-DOPA available to cross the blood-brain barrier. Since the 1970s, L-DOPA has been considered the gold standard for the treatment of Parkinson's disease; however, as the disease progresses, the side effects of L-DOPA increase. It is notable that the best available drug for the treatment of Parkinson's disease is one that was discovered more than 50 years ago.

The dopamine system in the brain can be divided into four distinct pathways--mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular--each with a unique function (Figure 2-12C) (Ungerstedt 1971). The *mesolimbic pathway* has cells located in the ventral tegmental area (VTA; A10 cell region) and projects to the ventral areas of the striatum, such as the nucleus accumbens. Dopamine release in the mesolimbic system is observed both with natural reinforcers (e.g., food, sex) and with most drugs of abuse. Dopamine transmission is thought to encode an error prediction signal wherein dopamine neurons fire when a reward is larger than predicted and show depressed activity when a reward is smaller than predicted (Schultz 1998). The *mesocortical pathway* also has its origin in the VTA and projects to the cerebral cortex, including limbic regions involved in cognition, such as the medial prefrontal cortex. The *nigrostriatal pathway* has cells located in the substantia nigra pars compacta (SNpc; A9 cell region) and provides dense innervation to the caudate and putamen,

where dopamine plays a significant role in movement. Indeed, the progressive and selective loss of dopamine neurons in the SNpc is a hallmark of Parkinson's disease. Finally, the *tuberoinfundibular pathway* consists of a population of dopamine neurons in the arcuate nucleus that inhibit prolactin release from the pituitary gland. The dopamine pathways are important from a therapeutic perspective; for example, blockade of the mesolimbic pathway is beneficial for the treatment of psychosis, but blockade of other dopamine pathways produces adverse effects (e.g., the EPS and hyperprolactinemia observed with some antipsychotic medications are due to blockade of the nigrostriatal and tuberoinfundibular pathways, respectively).

The activity of dopamine neurons can be regulated by both intrinsic properties and afferent pathways. Dopamine neurons exist in distinct states--an inactive state (hyperpolarized) and two active states (single spike and burst firing). On the basis of electrophysiological recordings in anesthetized rats, a model was proposed that differentiated tonic and phasic dopamine transmission (Grace 1991). This model posited that extrasynaptic dopamine levels are driven by the spontaneous (or tonic) firing of midbrain dopamine neurons, whereas synaptic dopamine levels are driven by periods of high-frequency activity, known as burst firing. The phasic burst firing of dopamine neurons and the accompanying release of synaptic dopamine normally occur in response to primary rewards (until they become fully predicted) and reward-predicting stimuli (Schultz 1998). A third dopamine neuron activity state--population activity--was demonstrated on the basis of the observation that a number of dopamine neurons (estimated at 50%) are not spontaneously active in vivo (Grace *et al.* 2007). The role of these silent dopamine neurons appears critical, given that they provide a gain of function to the dopamine signal. Through regulation of the number of spontaneously

active dopamine neurons, the magnitude of the dopamine signal (both tonic and phasic) can be manipulated. Aberrant regulation of this important gain of function is thought to contribute to the positive symptoms (i.e, paranoia, hallucinations, delusions) of schizophrenia (Grace *et al.* 2007).

Dopaminergic Receptors

Following early debates over the existence of multiple subtypes of dopamine receptors in the 1970s, classical pharmacological techniques provided evidence of the existence of two subtypes of dopamine receptors, D_1 and D_2 (Stoof and Kebabian 1984). It was subsequently determined that these two receptor subtypes each represent multiple receptors with similar characteristics. These receptors have been classified as D_1-like and D_2-like and consist of five identified dopamine receptors (D_1, D_2, D_3, D_4, and D_5), with D_1 and D_5 receptors being considered D_1-like and D_2, D_3, and D_4 receptors considered D_2-like. D_1-like receptors couple to stimulatory G proteins (G_s), which activate adenylyl cyclase, leading to production of the second messenger cAMP. In contrast, D_2-like receptors couple to inhibitory G proteins (G_i), which inhibit adenylyl cyclase and activate K^+ channels, resulting in membrane hyperpolarization. While it is often thought (and taught) that GPCRs exist and act as monomers, current evidence suggests that these receptors are capable of forming pharmacologically active homo- and heterodimers. Interestingly, dopamine receptors can form distinct heterodimer receptors, composed of both D_1-like and D_2-like subunits. These heterodimer receptors require binding of an agonist to both orthosteric binding sites for receptor activation. Moreover, whereas monomeric D_1-like and D_2-like receptors couple to G_s and G_i, respectively, D_1-D_2 receptor complexes are thought to signal predominantly through

$G_{q/11}$ protein and the Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) second-messenger system (Rashid *et al.* 2007). The discovery of heterodimer receptors not only provides a unique signaling mechanism for dopamine but also may have ramifications for pharmacotherapies targeting dopamine system function, such as the antipsychotic drugs. The D_1-like and D_2-like receptor classes also differ in their affinity for dopamine; D_2-like receptors have a significantly greater affinity for dopamine than do D_1-like receptors. This difference in receptor affinity suggests that dopamine signaling may depend on the type of dopamine neuron activity, with D_1 receptors primarily activated during periods of dopamine neuron burst firing and D_2-like receptors primarily activated by tonic dopamine. Thus, D_2-like receptors can respond to a broader range of stimuli.

Within the CNS, D_1-like and D_2-like receptors are largely concentrated in striatal regions (i.e., caudate, putamen, and nucleus accumbens), where they differentially regulate motor function. In addition, D_1-like receptors are present in limbic regions, including the amygdala and frontal cortex.

D_1-like receptors (D_1 and D_5). The D_1-like subgroup consists of D_1 and D_5 receptors. These two receptor types have similar pharmacological profiles and have been shown to couple to G_s or G_{olf} (a G protein originally thought to be present exclusively in olfactory tissue but now known to be present in limbic areas as well), resulting in activation of adenylyl cyclase and increases in intracellular cAMP. Thus, in general, the D_1-like receptors are excitatory, increasing the likelihood of firing of D_1-expressing medium spiny neurons. Receptors of the D_1-like family are intron-less in their respective coding regions. The presence of introns in a gene can lead to alternatively spliced transcripts where the exons are joined in different combinations. Thus, there

are no known alternative transcripts (c.f. the D_2-like receptors where alternative splicing directs the expression of multiple isoforms). D_1-like receptors are highly expressed in caudate and putamen, where they are localized to medium spiny neurons of the "direct pathway," which sends direct inhibitory projections to the ventral mesencephalon (substantia nigra pars reticulata [SNpr]/internal globus pallidus [GPi]). As described above (see "Dopaminergic System"), degeneration of dopamine neurons in the nigrostriatal pathway is a key pathology in Parkinson's disease, and L-DOPA has been the mainstay of treatment for Parkinson's disease for more than 50 years. Robust evidence from both preclinical and clinical studies suggests that targeted activation of dopamine D_1 receptors may be effective in treating Parkinson's disease as well as in ameliorating the side effects of L-DOPA therapy (Hall *et al.* 2019). Furthermore, given that L-DOPA depends on AADC for conversion to dopamine, the efficacy of L-DOPA decreases in late-stage Parkinson's disease, when loss of dopamine neurons results in loss of AADC. Several single-dose clinical studies of D_1 agonists have demonstrated strong antiparkinsonian effects on motor symptoms, and primate studies suggest that selective D_1 agonists may provide profound symptomatic relief even when the degree of nigrostriatal degeneration is so severe that current drugs are ineffective (Mailman *et al.* 2021). Unfortunately, early D_1 receptor agonists had pharmacological limitations and dose-limiting side effects (particularly hypotension and tachycardia) that precluded their clinical use. However, more recently developed compounds, such as the orally active selective D_1/D_5 partial agonist PF-06412562, display potential antiparkinsonian efficacy without producing overt changes in cardiovascular function (Huang *et al.* 2020; Papapetropoulos *et al.* 2018).

D_1 receptors. D_1 receptors are the predominant dopamine receptor in the frontal cortex, where they play a central role in higher-order functions such as working memory and cognitive flexibility (Goldman-Rakic 1995). Moreover, dopamine D_1 receptor expression or signaling is thought to be compromised in a variety of psychiatric disorders, including schizophrenia. Considerable research has been focused on developing D_1 agonists for the treatment of cognitive deficits in schizophrenia, given that these symptoms are not well treated by conventional antipsychotics. Overall, although increased signaling at dopamine D_1 receptors may improve cognitive function in schizophrenia, it is important to note that prefrontal dopamine transmission operates within a defined working range for effective cortical function, in which both increases and decreases can induce cognitive deficits. Despite the importance of the D_1 receptor as a therapeutic target, there has been a notable lack of clinically effective agents. The orally active selective D_1/D_5 partial agonist PF-06412562 (discussed earlier in the context of treatment for Parkinson's disease) demonstrates procognitive effects in preclinical models and is currently being evaluated for safety and efficacy in schizophrenia patients (Abi-Dargham *et al.* 2022).

D_5 receptors. The dopamine D_5 receptor was cloned in the early 1990s. This receptor, which shares about 80% homology with the D_1 receptor, also possesses signal transduction and pharmacology similar to those of the D_1 receptor; however, the D_5 receptor is reported to have a 10-fold higher affinity for the endogenous agonist dopamine. The D_5 receptor is neuron-specific and is located primarily in limbic areas of the brain. At present, there are no compounds that pharmacologically differentiate it from the D_1 receptor (Arnsten *et al.* 2017).

D_2-like receptors (D_2, D_3, and D_4). The D_2-like subgroup consists of D_2, D_3, and D_4 receptors. These three receptor types have similar pharmacological profiles and are largely coupled to G_i/G_o proteins.

D_2 receptors. D_2-like receptors are found on indirect pathway neurons that are indirectly connected to the GPi/SNpr through the globus pallidus pars externa (GPe) and the subthalamic nucleus (STN). Dopamine D_2-like receptors are found not only on postsynaptic targets but also on dopamine neurons themselves, both at the cell body and at the presynaptic nerve terminal. D_2-like receptors on dopamine neurons function as autoreceptors, and activation of the receptor can decrease neurotransmitter release and inhibit neuronal activity through well-known interactions with voltage-gated Ca^{2+} channels and GIRK channels. Because they contain introns within their coding regions, D_2-like receptors are structurally more complex than D_1-like receptors (i.e., the D_2 receptor contains six introns, the D_3

receptor five, and the D_4 receptor three). These introns give rise to distinct isoforms due to alternative mRNA splicing. Indeed, one important mechanism for modulating D_2 signaling is alternative splicing of an 87-base-pair exon between introns 4 and 5, resulting in long (D_{2L}) and short (D_{2S}) isoforms. Functionally distinct roles for D_{2S} and D_{2L} receptors have been proposed, based largely on characterization of mice lacking these isoforms. Such studies have suggested that the long isoform of the dopamine D_2 receptor is primarily located on postsynaptic medium spiny neurons in striatum and basal forebrain. In contrast, the short isoform is thought to contribute to the presynaptic regulation of dopamine release (De Mei *et al.* 2009). However, the individual contributions of the two isoforms to physiological and pathophysiological processes remain unclear. These isoforms differ in the third cytoplasmic loop, which plays a significant role in coupling the receptor to various intracellular partners. Thus, while both receptor isoforms signal through G_i proteins, differences in the downstream signaling of the two isoforms have been demonstrated. At present, there are no pharmacological tools that can differentiate the short and long forms of the two isoforms.

As discussed extensively elsewhere in this textbook (see Chapter 25, "Classic Antipsychotic Medications"), D_2 receptors have long been a focus in the treatment of psychosis. A significant literature from both human imaging and preclinical research has demonstrated that psychosis is associated with an increase in presynaptic dopamine bioavailability in the striatum (Howes *et al.* 2012). This increase in dopamine bioavailability is likely attributable to aberrant regulation of dopamine neuron activity in the VTA. This hypothesis is supported by the clinical efficacy of both first-and second-generation antipsychotics, which are largely defined by their high-affinity antagonism of the D_2 receptor. The second-generation (or atypical) antipsychotics are less likely to produce EPS, a characteristic thought to be associated with these agents' reduced affinity for the D_2 receptor with additional blockade of 5-HT_{2A} receptors.

D_3 receptors. In the 1990s, molecular cloning led to expansion of the dopamine receptor family beyond the existing D_1 and D_2

receptors. D_3 receptors have a more limited anatomical distribution than D_2 receptors, which makes them a potential novel target for development of drugs devoid of the EPS classically elicited by D_2 antagonists. Specifically, D_3 receptors are predominantly located in limbic areas, such as ventral striatum, thalamus, hippocampus, and cortex, and have a higher affinity for dopamine than do D_2 receptors. Furthermore, in contrast to both D_1 and D_2 receptors,

which are located either in perisynaptic sites or on dendrites and dendritic spines of medium spiny neurons, D_3 receptors appear to be localized to glutamatergic synapses (Sokoloff *et al.* 2013). Given their high affinity for dopamine and localization away from release sites, D_3 receptors appear to be well suited for detecting tonic, extrasynaptic dopamine transmission. Numerous studies have investigated the association between the dopamine D_3 receptor and schizophrenia. The D_3 receptor gene (*DRD3*) contains a polymorphism resulting in a serine-glycine substitution in the N-terminus of the receptor. Furthermore, a significant association has been demonstrated between the *DRD3* polymorphism and schizophrenia, with a meta-analysis of previous studies demonstrating significant associations (Dubertret *et al.* 1998). Thus, D_3 dopamine receptors are attractive targets for therapeutic intervention in schizophrenia due to their influence on dopamine system function and potentially positive effects on cognition. Indeed, results obtained from studies examining D_3 receptor antagonists indicate that blockade of D_3 receptors produces antipsychotic-like effects in rodent models used to evaluate both positive and negative symptoms (Maramai *et al.* 2016). Current clinical data from studies examining the efficacy of D_3 receptor antagonists/partial agonists in schizophrenia are inconclusive (Kiss *et al.* 2021), and additional studies are needed to separate the relative antipsychotic effects of D_2 and D_3 receptors.

D_4 receptors. The D_4 receptor has received much interest in psychopharmacological research because of the finding that clozapine has a high affinity for this receptor. Clozapine is the prototypical atypical antipsychotic, reported to be significantly more effective than 14 other antipsychotic drugs in a meta-analysis (Leucht *et al.* 2013). Clozapine's success led to the development of other selective D_4 (and D_4/5-HT_{2A}) receptor antagonists without EPS-inducing effects for use in the treatment of schizophrenia. Just 6 years after the discovery of the D_4 receptor, Merck published a series of manuscripts describing preclinical and clinical efficacy studies of L-745,870, a selective, CNS-penetrant, D_4-preferring antagonist (Bristow *et al.* 1997). Unfortunately, a third of the patients in this clinical trial discontinued the study due to a lack of therapeutic response, and the placebo group outperformed the D_4 antagonist group, with a subset of patients reporting worsening of symptoms. Similar disappointing results were observed in clinical studies of sonepiprazole, a highly selective D_4 receptor antagonist, which showed no benefits in schizophrenia patients (Corrigan *et al.* 2004). These findings dampened enthusiasm for the D_4 receptor as a therapeutic target for schizophrenia. Regrettably, the lack of clinical efficacy shown by these agents in CNS trials is a relatively common finding, with more than 90% of trials failing due to a lack of efficacy (sometimes associated with a high placebo response rate) (Gribkoff and Kaczmarek 2017). Indeed, failure rates are highest for drugs with a new mechanism of action (e.g., D_4 ligands) and for diseases whose etiology and pathogenesis have not been conclusively elucidated (e.g., schizophrenia). Nonetheless, research examining the potential utility of D_4 receptor ligands in other disorders, such as substance use disorders and L-DOPA-induced dyskinesia, is ongoing. This research is based on expression of the D_4 receptor in the human brain, which is predominantly localized to the cerebral cortex (including frontal cortex), hippocampus, and dorsal-medial thalamus. It should be noted that similar to the D_2 receptor gene, the D_4 receptor gene is highly polymorphic, with a variable number of tandem repeats of 48 nucleotides, ranging from 2 to 11 isoforms (D4.2-D4.11). The role of these isoforms in the pathophysiology of mental health disorders remains to be elucidated.

Dopamine Transporters

The primary mechanism for terminating the effects of dopamine signaling is uptake via the high-affinity DAT into the presynaptic terminal, where dopamine is either broken down enzymatically or repacked into vesicles via VMATs (German *et al.* 2015). Like SERT, DAT is a membrane-spanning protein. First cloned in 1991 (Giros *et al.* 1991; Kilty *et al.* 1991; Shimada *et al.* 1991), DAT is encoded by the gene *SLC6A3* (solute carrier family 6, member 3) and is located perisynaptically on dopamine nerve terminals as well as on somatodendritic sites within the VTA and the SNpc. Unlike SERT, DAT is present at its highest density in terminal field regions, including striatum, nucleus accumbens, and olfactory tubercle, and at its lowest density in cell body regions, including the VTA and the SNpc. Given the extrasynaptic location of DAT, dopamine neurotransmission also occurs in the form of paracrine signaling (Rice and Cragg 2008). As is the case for other monoamine transporters, DAT functions as a symporter, moving dopamine across the membrane using the concentration gradient of Na^+ (generated by the plasma membrane Na^+/K^+ ATPase) as the driving force. Like other neurotransmitter transporters, DAT can form oligomers (Jayaraman *et al.* 2021; Sorkina *et al.* 2021) and is tightly regulated by a complex array of signaling pathways (for comprehensive reviews of DAT structure, function, and regulation, see German *et al.* 2015; Kristensen *et al.* 2011; Pramod *et al.* 2013; Ramamoorthy *et al.* 2011; Ryan *et al.* 2021).

It is important to note that whereas the DAT is the primary mechanism terminating dopamine signaling, other transporters are able to transport dopamine across the membrane. For example, the PMAT and OCTs are nonselective cation transporters with relatively low affinity for monoamines but a high capacity to transport them. As discussed in the section on SERTs (see "Serotonin Transporters"), these transporters are being examined as potential targets for the development of novel antidepressant drugs (Daws 2009, 2021) as well as of treatments for psychostimulant use disorder (Maier *et al.* 2021). In the medial frontal cortex, dopamine is taken up predominantly by the NET, a circumstance that goes against the former dogma that transporters selectively move only their respective neurotransmitter (Moron *et al.* 2002). More importantly, this transporter promiscuity has potential therapeutic relevance in that norepinephrine reuptake inhibitors (e.g., the antidepressants desipramine and venlafaxine) may lead to increases in dopamine levels within the prefrontal cortex (Tanda *et al.* 1994). Indeed, a role for dopamine in depression is supported by the effectiveness of the atypical antidepressant bupropion, which is chemically unrelated to other classes of antidepressant agents. Bupropion is a relatively weak dopamine and norepinephrine reuptake inhibitor, with efficacy comparable to that of other antidepressants. DAT is also a primary target for psychomotor stimulants, where drugs such as amphetamine and cocaine act to inhibit DAT function, resulting in increases in extracellular dopamine. A large, rapid increase in dopamine signaling is thought to underlie the euphoria (or "high") associated with stimulant drugs when they are administered via inhalation or nasal insufflation.

The increasing availability of whole-genome sequencing has led to the observation that genetic polymorphisms in the DAT gene (which influence the expression and/or

function of the transporter) are associated with neuropsychiatric disorders such as attention-deficit hyperactivity disorder (ADHD), Parkinson's disease, schizophrenia, and substance use disorders (German *et al.* 2015; Gowrishankar *et al.* 2014). The DAT is also a pharmacological target, particularly for treatment of ADHD, one of the most common neurobehavioral disorders in children, which affects academic achievement and social interactions. When administered at low dosages in a sustained-release formulation, stimulant medications (e.g., amphetamine and methylphenidate) can effectively treat symptoms of ADHD, with an effect size comparable to, if not better than, those of most other psychiatric medications (Leucht *et al.* 2012). In children with ADHD, DAT inhibitors have been demonstrated to increase dopamine levels, resulting in improvements in attention and task-oriented behavior (Drechsler *et al.* 2020).

DAT is a key regulator of dopaminergic neurotransmission. Gene variants in DAT expression and/or function that cause perturbed dopamine signaling are associated with a number of psychiatric and motor disorders, as well as with substance use disorders. DAT and its many regulators, as well as other transporters for dopamine, are the focus of continued research efforts to better understand the etiology of these disorders and their treatment.

Noradrenergic System

Norepinephrine, also known as noradrenaline, is a neurotransmitter present in the CNS and the peripheral sympathetic nervous system that plays an essential role in the regulation of arousal, attention, cognitive function, and response to stress. Norepinephrine (see Figure 2-1) is a monoamine synthesized from the amino acid L-tyrosine within neurons that express the enzymes tyrosine hydroxylase and dopamine b-hydroxylase; briefly, dietary L-tyrosine permeates the blood-brain barrier and is transported to neuronal presynaptic terminals, where it is converted to L-DOPA by tyrosine hydroxylase (i.e., the rate-limiting step). L-DOPA is then decarboxylated by AADC to produce dopamine. Finally, in neurons that contain the enzyme dopamine b-hydroxylase, dopamine is converted to norepinephrine; cells that contain the enzyme phenylethanolamine-*N*-methyl transferase are also able to convert norepinephrine to epinephrine (Figure 2-13).

FIGURE 2-13. The noradrenergic system *(opposite page)*.

See Plate 12 to view this figure in color.

(A) Noradrenergic neurons of the locus coeruleus are located in the pons of the brain stem. **(B)** Synthesis of norepinephrine (NE) starts with the amino acid L-tyrosine, which is actively transported into presynaptic NE nerve terminals from extracellular fluid. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts L-DOPA to dopamine. Dopamine is then packaged into vesicles, by vesicular monoamine transporters (VMATs), and hydroxylated by dopamine b-hydroxylase (DBH) in the presence of O_2 and ascorbate to form NE. Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal a_2 adrenoreceptors, respectively. Binding of NE to G proteins (G_o, G_i, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C beta (PLCb) produces a cascade of second-messenger and cellular effects. NE's action is terminated when it is taken back into the presynaptic neuron via NE transporters (NETs). (Note that NETs are located extrasynaptically, not synaptically [as depicted in figure].) Once inside the neuron, NE can either be repackaged into vesicles for reuse or undergo enzymatic degradation. AMPT = a-methyl-*p*-tyrosine; cAMP = cyclic adenosine monophosphate; COMT = catechol-O-methyltransferase; DA = dopamine; DAG = diacylglycerol; IP_3 = inositol 1,4,5-triphosphate; MAO = monoamine oxidase; MHPG = 3-methoxy-4-hydroxyphenylglycol; NM = normetanephrine.

Norepinephrine in the CNS controls arousal and alertness and influences cognitive functions such as working memory, fear memory retrieval, attention, and spatial learning. In addition to these actions in the CNS, norepinephrine and epinephrine released in the periphery by the sympathetic nervous system and neuroendocrine chromaffin cells in the adrenal medulla are crucial in preparing the body for the "fight or flight" stress response through modulation of several physiological outputs, such as cardiovascular function, gastrointestinal motility and secretion, bronchiole dilation, and glucose metabolism.

Within the CNS, the main clustering of norepinephrine-producing neurons lies in the locus coeruleus (Latin meaning "blue spot"--named for its bluish appearance in nonstained brain tissue, due to the presence of melanin granules in these neurons) (Schwarz and Luo 2015). The locus coeruleus, located in the pons, is responsible for approximately 90% of norepinephrine innervation of forebrain and produces more than 70% of all norepinephrine in the brain (see Figure 2-13). The widespread efferent innervation of the locus coeruleus suggests that the noradrenergic system, rather than having a specific role in sensory or motor outputs, plays a modulatory and integrative

role by regulating the "signal-to-noise ratio" of other neuronal systems, either excitatory or inhibitory. The net result is an enhancement of synaptic transmission in the target circuits that regulate wakefulness and arousal and facilitate sensory signal detection; indeed, increased activity in locus coeruleus neurons and increased norepinephrine release are observed especially in response to physiological or environmental challenges and stressful stimuli (Jacobs *et al.* 1991; Morilak *et al.* 2005). For this reason, modulation of the noradrenergic system has classically been considered central to stress responsivity. However, it is also clear that the noradrenergic network has a role in regulation of a wide range of core cognitive functions, including attention, working memory, and behavioral flexibility (Sara 2009; Valentino and Van Bockstaele 2008).

The locus coeruleus was originally considered to be a homogeneous group of neurons, but technological advances in neuronal tracing, optogenetics, chemogenetics, electrophysiology, and genetic fate mapping have revealed that the locus coeruleus is likely divided into distinct subgroups of cells that receive selective inputs from other brain regions and have relatively circumscribed projection targets in the forebrain. Notably, locus coeruleus neurons that project to functionally related forebrain regions tend to display synchronous firing activity (Chandler *et al.* 2019; Totah *et al.* 2019). The various subpopulations of locus coeruleus neurons also appear to express developmentally distinct genetic markers. Thus, the specificity of noradrenergic signaling in the brain may result not only from specific adrenergic receptors present on postsynaptic elements of target cells but also from diverse ensembles of locus coeruleus neurons and their specific integration within different functional networks (Poe *et al.* 2020).

Dysregulation of the noradrenergic system alters the response to stress, can increase anxiety, and produces cognitive and behavioral deficits associated with a number of psychopathologies, including Alzheimer's and Parkinson's diseases, ADHD, and schizophrenia (Borodovitsyna *et al.* 2017). It is therefore not surprising that modulation of locus coeruleus activity is important for maintaining effective cognitive function and stress responsivity. The pro-stress neuropeptide corticotropin-releasing factor (CRF) is a key regulator of the locus coeruleus-norepinephrine system. Preclinical studies have found that acute release of CRF from amygdala terminals projecting to the locus coeruleus that occurs after an acute stress exposure increases locus coeruleus neuron firing and promotes an adaptive response by increasing vigilance and behavioral flexibility. Conversely, chronic CRF release and tonic stimulation of locus coeruleus-norepinephrine neurons increase anxiety and depressive-like behaviors (McCall *et al.* 2015; Valentino and Van Bockstaele 2008). Moreover, studies have found that in comparison with males, females show increased sensitivity of locus coeruleus neurons to the effects of CRF, which may help to explain the increased incidence of posttraumatic stress disorder (PTSD) and depressive disorders in human females (Bangasser *et al.* 2016). Another regulator of the noradrenergic system that has attracted attention recently is the endocannabinoid system, which acts as an antistress modulator, potentially by decreasing release of CRF in locus coeruleus afferents (Wyrofsky *et al.* 2019). Finally, it is notable that the locus coeruleus itself also releases neuropeptides such as galanin, neuropeptide Y, cocaine-and amphetamine-regulated transcript, and BDNF; additionally, locus coeruleus-norepinephrine neurons can release dopamine (Beas *et al.* 2018).

Norepinephrine Receptors

Norepinephrine's actions are mediated by a-adrenergic receptors (a_1-ARs and a_2-ARs) and b-adrenergic receptors (b_1-ARs, b_2-ARs, and b_3-ARs), all of which are GPCRs (Table 2-3). In general, a_1-ARs and b-ARs enhance neurotransmission and plasticity, promoting stimulatory effects in the CNS, whereas a_2-ARs have inhibitory effects, such as reducing norepinephrine release and decreasing neuronal excitability. Nonselective agonists bind to ARs with different affinities, and include norepinephrine and dopamine (both of which bind to a_1, a_2, and b_1 ARs) as well as epinephrine (which binds to all classes of ARs).

Alpha$_1$ receptors further subdivide into a_{1A}, a_{1B}, and a_{1D} adrenergic receptors. These receptors are located postsynaptically in brain regions including the locus coeruleus, olfactory bulb, cerebral cortex, dentate gyrus, amygdala, and thalamus. a_1-ARs have intermediate binding affinity to norepinephrine and couple to Ga_q proteins that activate PLC. PLC converts phosphatidylinositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol on the cell membrane. IP_3 is released to the cytosol and binds to transmembrane IP_3 receptors located on the endoplasmic reticulum, which functions as a channel to release calcium from the endoplasmic reticulum to the cytosol. Diacylglycerol remains in the cell membrane and activates PKC, which phosphorylates other proteins. These combined effects produce excitatory cellular effects. Prazosin is an antagonist of a_1-ARs that has been approved for treatment of hypertension and has shown promising effects in treatment of PTSD-associated nightmares (Akinsanya *et al.* 2017). Additionally, in preclinical studies, a_1-AR antagonists (i.e., prazosin, terazosin, and WB-4101) decreased stimulant drug-induced locomotor hyperactivity (a predictor of drug abuse liability) (Schmidt and Weinshenker 2014). Human studies have shown that prazosin and doxazosin (another a_1-AR antagonist) can be effective as potential treatments for alcohol use disorder (Farokhnia *et al.* 2019).

Alpha$_2$ receptors--subdivided into a_{2A}, a_{2B}, and a_{2C} adrenergic receptors--have the highest binding affinity for norepinephrine among the different subtypes of noradrenergic receptors. Alpha$_2$ receptors are located both presynaptically and postsynaptically in brain regions including the locus coeruleus, amygdala, and hypothalamus. These receptors couple to the $Ga_{i/o}$ proteins, which inhibit adenylate cyclase and lower the production of cAMP, producing inhibitory cellular effects. In noradrenergic neurons, a_2 receptors act as autoreceptors (i.e., norepinephrine binding to a_2-ARs in presynaptic noradrenergic terminals prevents further release of norepinephrine). Therefore, activation of these receptors lowers noradrenergic signaling. Other agonists of a_2-ARs include methyldopa, guanfacine, and clonidine. In line with the general idea that a_2-ARs act in opposition to a_1-ARs, activation of a_2-ARs produces beneficial effects on substance-related and addictive disorders; for example, clonidine significantly increases smoking abstinence rates and alleviates alcohol and opioid withdrawal symptoms (Haass-Koffler *et al.* 2018; Srivastava *et al.* 2020; Vanderkam *et al.* 2021). Clonidine and guanfacine have also been used as medications to treat ADHD (Chan *et al.* 2016). Dexmedetomidine, a highly selective a_2-AR agonist that is used in anesthesia in general surgery, may also have a use in management of neuropathic pain (Zhao *et al.* 2020). In general, however, use of a_2-AR agonists in psychiatric disorders may be limited by their potential to cause hypotension and sedation. Antagonists of these receptors, such as clozapine, mirtazapine, and idazoxan, have been used in clinical treatment as antidepressants and antipsychotics; the mechanism of these therapeutic effects has in part been attributed to blockade of a_2-ARs on serotonergic and dopaminergic terminals, resulting in modulation of these systems. In addition, a_2-AR antagonists such as clozapine are not selective for adrenergic receptors and may produce therapeutic effects by virtue of direct interactions with serotonin and dopamine receptors (Langer 2015).

Beta-adrenergic receptors--subdivided into b_1-, b_2-, and b_3-ARs--have the lowest binding affinity for norepinephrine among the different subtypes of noradrenergic receptors. b_1-ARs and b_2-ARs are most prevalent in the CNS, whereas b_3-ARs are mainly expressed in adipose tissue. When b-ARs couple to the Ga_s protein signaling pathway, cAMP levels increase, leading to activation of PKA and producing excitatory cellular effects. b-ARs in the periphery are activated during stress and are responsible for causing increased heart rate (b_1-ARs) and increased pulmonary function (b_2-ARs). b-AR antagonists (e.g., labetalol) include lipophilic molecules that permeate the blood-brain barrier (e.g., propranolol) and hydrophilic molecules with less CNS penetrability (e.g., atenolol, nadolol). b-AR blockers have been used to manage symptoms of agitation and restlessness in schizophrenia and anxiety disorders and to reduce acute performance anxiety; given that improvements were obtained with both blood-brain-permeable (propranolol) and nonpermeable (atenolol, nadolol) antagonists, it is likely that these effects were due to attenuation of the cardiovascular response to catecholamines rather than representing specific CNS effects. In addition to providing these effects, b-AR antagonists may also be useful as adjunctive therapy to treat phobias and to suppress recall of traumatic memories in PTSD (Boyce *et al.* 2021).

Norepinephrine Transporters

As is also the case for the serotonin and dopamine systems, the high-affinity NET is the primary mechanism terminating noradrenergic neurotransmission. Once it is returned to the nerve terminal, norepinephrine is either broken down enzymatically or repackaged into vesicles via VMAT2. NET is located extrasynaptically (Miner *et al.* 2003) and is richly expressed in the cell body region, the locus coeruleus, with lower density in terminal regions, including hippocampus, amygdala, cortex, and hypothalamus (Tejani-Butt 1992). As is the case for SERT and DAT, NET is a symporter, using the sodium gradient generated by the plasma membrane Na^+/K^+ ATPase to carry norepinephrine molecules into the intracellular compartment. Like its monoamine transporter relatives, NET can form oligomers (Jayaraman *et al.* 2021) and is regulated

by a variety of intracellular and extracellular signaling molecules (Mandela and Ordway 2006). First cloned in 1991 (Pacholczyk *et al.* 1991), NET is a member of the SLC6 family and is encoded by the gene *SLC6A2* (for comprehensive reviews of NET structure, function, and regulation, see Mandela and Ordway 2006, Kristensen *et al.* 2011, Ramamoorthy *et al.* 2011, and Pramod *et al.* 2013).

The noradrenergic system plays an important role in control of mood and arousal states, as well as cardiovascular function. Dysfunction in noradrenergic neurotransmission is linked to a number of psychiatric disorders, including depression and ADHD, as well as to orthostatic intolerance and cardiovascular diseases. These disorders are treated (with varying success) with drugs that block NET and lead to increased extracellular norepinephrine, such as desipramine, nisoxetine, reboxetine, atomoxetine, nomifensine, and mazindol (Kristensen *et al.* 2011; Zhou 2004). As noted in previous transporter sections, monoamine transporters are promiscuous (Daws 2009); thus, blockers of NET also serve to increase extracellular serotonin and dopamine to some extent. In addition, OCTs and PMAT are able to transport norepinephrine with low affinity but high capacity, meaning that when extracellular levels of norepinephrine are elevated, OCTs and PMAT can efficiently remove norepinephrine from the extracellular compartment. Studies using OCT2 knockout mice have provided evidence for an important role of this transporter in clearance of norepinephrine and in the antidepressant efficacy of NET-targeting antidepressants such as reboxetine and venlafaxine (Bacq *et al.* 2012). Consistent with these findings, Bowman *et al.* (2020) found that the nonselective OCT blocker decynium-22 enhanced the antidepressant effects of the NET blocker desipramine in mice (see also Daws 2021).

Numerous gene variants of NET have been identified and have been linked to various disorders, although the literature is inconclusive. For example, some studies (e.g., Haenisch *et al.* 2009) have reported evidence suggesting that some variants are associated with depressive disorders, whereas a meta-analysis of existing research reported mixed findings on this association (Zhao *et al.* 2013). NET gene variants have also been associated with ADHD (Hahn *et al.* 2009; Kim *et al.* 2008) and cardiovascular disorders (Hahn *et al.* 2005; Halushka *et al.* 1999; Shirey-Rice *et al.* 2013). NET, like SERT and DAT, continues to be studied both as a source of information on the etiological bases of mental disorders and as a transporter that can be targeted to improve treatment of these disorders.

Cholinergic System

Acetylcholine (ACh) is the neurotransmitter of the parasympathetic nervous system. Indeed, its discovery in 1921 by Otto Loewi as the chemical neurotransmitter from the vagus nerve (hence "Vagusstoff," the name given by Loewi) was the seminal demonstration of chemical synaptic transmission. But ACh also has major roles as a neurotransmitter in the brain, particularly with respect to regulation of learning and memory, motor activity, reward, and cognition. ACh is a choline molecule that has been acetylated at the oxygen atom (see Figure 2-1).

In nerve terminals, ACh is synthesized from acetyl coenzyme A and choline by the enzyme choline acetyltransferase (ChAt). However, the rate of ACh synthesis is limited not by the enzyme activity of ChAt but rather by the uptake of choline into neurons by a high-affinity Na^+-dependent uptake pump. This uptake pump can be blocked by hemicholinium-3, resulting in depletion of ACh. In the CNS, the highest activity of ChAt is found in the caudate nucleus, retina, interpeduncular nucleus, and spinal roots. As discussed elsewhere in this chapter, *transporters* are the primary proteins terminating the activity of most neurotransmitters. By contrast, enzymatic degradation of ACh by the enzyme acetylcholinesterase (AChE) terminates the synaptic activity of ACh, although a high-affinity choline transporter also participates. AChE is one of the most efficient enzymes known; the catalysis of released ACh occurs within a submillisecond time frame. This catalysis is essential in the skeletal neuromuscular junction to allow the next volley of released ACh to trigger a postsynaptic excitatory potential. AChE (Enzyme Commission [EC] number 3.1.1.7) is distinguished from butyrylcholinesterase (BChE; EC 3.1.1.8) by its catalytic selectivity for ACh over butyrylcholine hydrolysis. AChE is synthesized in nerve, muscle, and certain hematopoietic cells. In excitable tissues, AChE is localized on the extracellular surface of both nerve and muscle; in the neuromuscular junction of skeletal muscle, AChE is synthesized by the muscle rather than the nerve cell. Therapies aimed at increasing the function of ACh do so primarily by inhibiting AChE; these drugs are used in the treatment of Alzheimer's disease, myasthenia gravis, glaucoma, smooth muscle atony, and other disorders of autonomic nervous system functions. Such drugs are also used as insecticides and chemical warfare agents (i.e., nerve gases), which cause paralysis of respiratory muscles, primarily the diaphragm, leading to death.

In the brain, cholinergic neurons function both as interneurons (in areas such as the caudate-putamen and nucleus accumbens) and as projection neurons connecting brain areas (e.g., a tract from the septum to the hippocampus). There are eight cholinergic nuclei from which cholinergic neurons originate and send ascending projections to areas such as the nonstriatal telencephalon; descending projections innervate areas such as the pontine and medullary reticular formations, deep cerebellar and vestibular nuclei, and cranial nerve nuclei (Mesulam *et al.* 1984; Satoh and Fibiger 1985). The cholinergic nucleus basalis of Meynert is particularly susceptible to early degeneration in Alzheimer's disease (Theofilas *et al.* 2015). Such observations provide the rationale for cholinergic therapy in mild to moderate Alzheimer's disease.

Cholinergic Receptors

Studies with two alkaloids, nicotine and muscarine, formed the initial basis for subtyping of cholinergic receptors (Dale 1914). Further support for at least two classes of cholinergic receptors, nicotinic and muscarinic, was obtained from studies on the selective effects of the nicotinic ACh receptor antagonist D-tubocurarine on nicotinic responses and of the muscarinic ACh receptor antagonist atropine on muscarinic responses. Five subtypes of muscarinic receptors, m_1-m_5, have been cloned. These receptors are G protein coupled and are widespread in the CNS. The ACh receptor antagonist pirenzepine has high affinity for the m_1 receptor subtype, which predominates in the hippocampus and cerebral cortex, whereas receptors with low affinity for pirenzepine predominate in the cerebellum and brain stem. Muscarinic receptor/G protein interactions can initiate different types of signal transduction mechanisms: 1) inhibition of adenylyl cyclase; 2) stimulation of phosphoinositide hydrolysis via activation of phospholipase C; and 3) regulation of an ion channel, particularly a specific K^+ conductance (Nathanson 1987). Phosphoinositide hydrolysis yields two second messengers, inositol triphosphate and diacylglycerol.

Many of the early psychotherapeutic drugs (e.g., the first-generation antipsychotic chlorpromazine or the TCA imipramine)--and even some of the newer atypical antipsychotics (e.g., clozapine, olanzapine) (Bymaster *et* *al.* 2003)--block muscarinic receptors to produce adverse effects. Such anticholinergic effects may include dry mouth, mydriasis (causing blurred vision), tachycardia, hot and flushed skin, constipation, urinary retention, agitation, and even delirium. A mnemonic for remembering these effects is "red as a beet, dry as a bone, blind as a bat, and mad as a hatter." Patients find these effects quite unpleasant, and they are a common reason that patients discontinue drug use. From a therapeutic perspective, it is now established that muscarinic receptors regulate behaviors such as cognition, learning and memory, reward, and movement, so that there is increasing interest in targeting these receptors to treat various brain disorders, particularly Alzheimer's disease but also schizophrenia (Moran *et al.* 2019).

The nicotinic cholinergic receptor (nAChR) was the first neurotransmitter receptor to be purified to homogeneity. NAChR is an ionotropic receptor with five subunits arranged across the membrane like a doughnut, with the central hole representing the ion channel. Activation of the receptor results in opening of the channel, which has cation selectivity. Neuronal nicotinic receptors contain a and b subunits, with the a subunit having eight different isoforms and the b subunit having three. ACh binding to the a_1 subunit causes activation of the nicotinic receptor. Although ACh is still present at the receptor, the response of neuronal nicotinic receptors diminishes very rapidly, due to the process known as desensitization. Phosphorylation of the receptor by several kinases increases the rapid phase of receptor desensitization. A major function of nAChRs is modulation of excitatory transmission through a presynaptic action. Succinylcholine is a partial agonist of nAChRs and is routinely used during surgery as a muscle relaxant. The arrow-tip poison curare, the active ingredient of which is D-tubocurarine, is an nAChR antagonist. Curare causes death by asphyxia due to paralysis of skeletal muscles. Of interest, it was the use of curare by Claude Bernard in the mid-nineteenth century that first demonstrated a locus of drug action near or at the neuromuscular junction.

Like other drugs of abuse, nicotine stimulates release of dopamine in the nucleus accumbens, and this action is thought to account for its reinforcing properties. The release of dopamine occurs due to stimulation of nicotinic receptors in the VTA and the nucleus accumbens, particularly the $a_4/a_6/b_2$* subtype in the VTA (Picciotto and Mineur 2014). The effective smoking-cessation medication varenicline is a high-affinity partial agonist at this subtype. Varenicline also produces rewarding effects that mitigate the feelings of withdrawal and craving that accompany cessation of smoking (Jordan and Xi 2018).

Glutamatergic System

Glutamate (see Figure 2-1) is the primary excitatory amino acid neurotransmitter in the mammalian CNS and is present in high concentrations throughout the brain. It is responsible for fast excitatory neurotransmission via activity at ionotropic glutamate receptors as well as for initiating intracellular cascades that regulate synaptic plasticity (both long-term potentiation [LTP] and long-term depression [LTD]) and memory. While glutamate plays a central role in excitatory neurotransmission, aberrant glutamatergic signaling is also observed in pathological conditions, and excess glutamate

can be toxic, leading to neuronal death (excitotoxicity). Given the potential for toxicity, glutamate levels in the brain are tightly controlled. As a nonessential amino acid that cannot cross the blood-brain barrier, glutamate is synthesized in the brain, and its metabolism is complex and compartmentalized (Figure 2-14). In contrast to monoamines, whose synthesis and reuptake occur in the neuron, glutamatergic transmission is regulated by astrocytes. Neurons lack the enzyme pyruvate carboxylase and therefore cannot synthesize glutamate through the tricarboxylic acid cycle (also known as the Krebs cycle). Astrocytes generate glutamate via de novo synthesis or by reuptake and recycling of released g-aminobutyric acid (GABA) and glutamate. De novo synthesis requires transamination of the tricarboxylic acid cycle product a-ketoglutarate, which is converted to glutamine by glutamine synthetase, an enzyme predominantly located in astrocytes. Glutamine is then transported (via sodium-coupled neutral amino acid transporters) from the astrocytes to neurons, where it functions as a substrate for the synthesis of both glutamate and GABA (the primary inhibitory amino acid neurotransmitter in the mammalian CNS). In neurons, the enzyme glutaminase converts glutamine back to glutamate, which is then packaged into vesicles via vesicular glutamate transporters (see Figure 2-14). Glutamate released from presynaptic terminals must be rapidly removed to avoid excitotoxicity. The major mechanism for this process is uptake into pre-and postsynaptic neurons as well as uptake by the surrounding astrocytes. The transporters responsible for this uptake are the Na^+-dependent excitatory amino acid transporters ($EAATs_{1-5}$). These transporters are differentially expressed in specific cell types, with $EAAT_1$ and $EAAT_2$ being found primarily in astrocytes and responsible for most of the glutamate reuptake, and $EAAT_3$ being localized on both excitatory and inhibitory neurons. These transporters play a critical role in maintaining extracellular glutamate concentrations and have been shown to be impaired following brain injury (e.g., stroke, trauma). Excitotoxicity is a consequence of sustained glutamatergic transmission and the associated excessive influx of Ca^{2+}. The resulting calcium overload is particularly neurotoxic, leading to activation of catabolic enzymes (e.g., calpain) that trigger a cascade of events leading to cell death (i.e., apoptosis or necrosis) (Lipton 1999).

Glutamatergic Receptors

Glutamatergic receptors in the CNS can be classified into two major subtypes: ligand-gated ion channel (ionotropic) receptors and G protein-coupled (metabotropic) receptors (Figure 2-15).

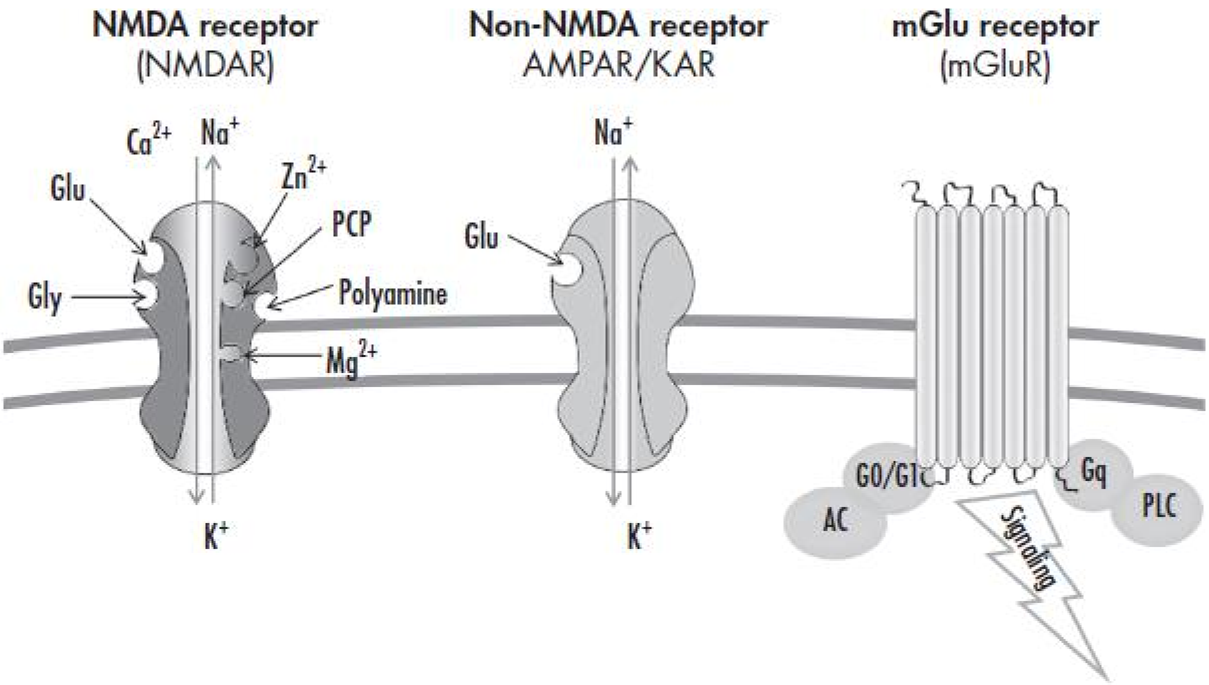

FIGURE 2-15. Glutamatergic receptors.

See Plate 13 to view this figure in color.

Ionotropic glutamate receptors mediate fast excitatory signaling in the brain; however, glutamate also plays a modulatory role through activation of metabotropic receptors. The a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors (AMPAR and KAR) are activated by glutamate and are permeable to Na^+, which results in a rapid, transient depolarization of the plasma membrane. In contrast, *N*-methyl-D-aspartate (NMDA) receptors are more complex, being blocked by Mg^{2+} at hyperpolarized membrane potentials and permeable to Ca^{2+}, permitting activation of various intracellular cascades. AC = adenylyl cyclase; G0/G1, Gq = Gi/o protein a subunits; PLC = phospholipase C; PCP = phencyclidine.

Ionotropic glutamate receptors.

The ionotropic glutamate receptors mediate fast excitatory neuronal transmission in the CNS and can be divided into three distinct classes on the basis of their affinity for three different synthetic ligands: 1) a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), 2) NMDA, and 3) kainate (see Figure 2-15). However, glutamate can bind to all three classes with equal affinity. In the adult mammalian brain, NMDA and AMPA glutamatergic receptors are co-located in approximately 70% of the synapses (Bekkers and Stevens 1989).

AMPA receptors. As is true for all ionotropic glutamate receptors, AMPA receptors are tetrameric, cation-permeable receptors expressed widely throughout the brain. There are four AMPA receptor subunits (GluA1-4), which are assembled as dimers-of-dimers to form a tetrameric receptor. The AMPA receptor is activated by two molecules of glutamate, resulting in a conformational change and rapid channel opening.

Once channels are open, AMPA receptors carry a large inward sodium current that rapidly terminates, resulting in a fast, transient excitatory synaptic signal. It should be noted that the GluA2 subunit possesses a positively charged arginine in the pore-forming region, which prevents Ca^{2+} influx. Because of this characteristic, the majority of GluA2-containing AMPA receptors are considered Ca^{2+}-impermeable. In contrast, AMPA receptors that lack a GluA2 subunit are Ca^{2+}-permeable and may play a role in synaptic plasticity (Isaac *et al.* 2007).

Given the role of AMPA receptors in mediating fast synaptic signaling, changes in the number, location, and phosphorylation of these receptors can produce significant alterations in synaptic strength. The best-known modulation of synaptic strength is the concept of *long-term potentiation* (LTP), a form of cellular memory wherein large, transient increases in excitatory transmission (induced by a variety of electrical, pharmacological, and behavioral mechanisms) lead to an increase in the number of synaptic AMPA receptors and sustained increases in synaptic strength. The converse of LTP is known as *long-term depression* (LTD), in which persistent, low-frequency activation produces a decrease in synaptic strength as a result of a reduction in the number of synaptic AMPA receptors. The mechanisms associated with LTP and LTD are complex; however, the phosphorylation states of the AMPA receptor subunits are directly altered by protein kinases and phosphatases. During LTP, phosphorylation of the receptor subunits enhances the receptor's interaction with proteins that modulate the membrane trafficking and synaptic targeting of the receptor (Malinow and Malenka 2002). Similarly, activation of phosphatases results in the removal of AMPA receptors from the synapse and forms the basis of LTD.

Kainate receptors. The kainate receptor possesses properties similar to those of the AMPA receptors, being a ligand-gated cation channel permeable to Na^+ and K^+. Because of their similarities and the lack of pharmacological tools to distinguish them, kainate and AMPA receptors were previously grouped together and referred to as non-NMDA receptors. The kainate receptors are multimeric assemblies composed of combinations of low-affinity subunits (GluK1, GluK2, and GluK3) and high-affinity subunits (GluK4 or GluK5) (these subunits were formerly known as GluR5, GluR6, GluR7, KA1, and KA2, respectively) that form a tetrameric complex (Mayer 2021). GluK1-GluK3 may form functional homomeric or heteromeric receptors, whereas GluK4 and GluK5 form functional receptors only when paired with the GluK1-GluK3 subunits. Until recently, relatively little was known about the functional and physiological roles of kainate receptors. Based on the observation that intraperitoneal injections of kainate produce severe seizures and neurotoxicity in preclinical models, the kainate receptors have classically been implicated in epileptogenesis (Ben-Ari and Cossart 2000). These seizurogenic properties suggest that kainate receptor antagonists might have clinical utility as anticonvulsants and neuroprotectants. Indeed, preclinical studies have demonstrated that kainate receptor antagonists display antiepileptic activity in preclinical models of epilepsy; however, the efficacy of kainate receptor antagonists has not yet been examined clinically due to a lack of appropriate pharmacological compounds.

Kainate receptors are widely distributed throughout the brain, with high expression observed throughout the hippocampus, a key structure involved in memory consolidation and a site of pathology in temporal lobe epilepsy. Within the hippocampus, GluK1 subunits are highly expressed on GABAergic interneurons, whereas GluK2 subunit-containing kainate receptors are primarily located on excitatory pyramidal neurons (Falcon-Moya *et al.* 2018). This differential localization allows kainate receptors to have fine control over neural circuits in the hippocampus. In addition, the kainate receptor appears to have a unique signaling mechanism, other than its ionotropic effects, by which kainate regulates hippocampal function. This noncanonical signaling takes place by means of an unconventional metabotropic mechanism involving G protein signaling. Specifically, presynaptic inhibition of GABA release by kainate is dependent on G protein activation and PKC activity. A similar noncanonical mechanism was observed in dorsal root ganglion neurons, where it was demonstrated that the effects of kainate are independent of ion channel function (Rozas *et al.* 2003). Although this metabotropic effect of kainate receptor function is relatively well established, the molecular mechanisms underlying noncanonical signaling require further elucidation.

The advent of genetic knockout mice has enabled investigation of the biological functions of the kainate receptor, even when pharmacological tools are lacking. For example, in a series of studies investigating the role of GluK2 in rodent behaviors, GluK2 knockout mice were hyperactive and extremely aggressive, took more risks, and consumed excessive amounts of sweetened water (Shaltiel *et al.* 2008). This phenotype was consistent with phenotypes of mania observed in patients with bipolar disorder. Interestingly, some of the aberrant behaviors observed in the GluK2 knockout mice were reversed by long-term lithium administration, suggesting the potential involvement of kainate receptors in the pathophysiology of bipolar disorder (Shaltiel *et al.*

2008). Indeed, polymorphisms associated with GluK2 (6q16.3-q21) may contribute to an increased risk of mood disorders.

***NMDA receptors*.** As is also the case for the AMPA and kainate receptors, NMDA receptors are tetrameric, cation-permeable ionotropic glutamate receptors expressed widely throughout the brain. Functional NMDA receptors are typically composed of two GluN1 and two GluN2 subunits; however, there are one GluN1, four GluN2, and two GluN3 subunit-encoding genes, and alternative splicings of each gene can produce additional variants. The NMDA receptor is activated by two molecules of glutamate, and this activation requires the presence of the co-agonist glycine (or D-serine). The binding site for glutamate has been localized to the GluN2 subunit, and the site for the co-agonist glycine has been localized to the GluN1 subunit. Activation of the NMDA receptor results in a conformational change and the opening of a nonselective cation channel, allowing a voltage-dependent flow of sodium (Na^+) and calcium (Ca^{2+}) ions into the cell. It should be noted that binding of both glutamate and glycine is not sufficient for ion flow across the NMDA receptor channel because at resting membrane potential, the NMDA ion channel is blocked by magnesium (Mg^{2+}) ions. Like Ca^{2+}, Mg^{2+} is a divalent cation that is present at millimolar concentrations in the extracellular space. Upon NMDA receptor opening, Mg^{2+} enters the NMDA receptor pore, but unlike Ca^{2+} ions, Mg^{2+} ions bind tightly and prevent ion flow. This Mg^{2+} blockade is removed only when the membrane is sufficiently depolarized (e.g., by activation of AMPA and kainate receptors on the same postsynaptic neuron). As a result, the NMDA receptor acts as a molecular coincidence detector, requiring both a sufficiently strong depolarization and the synaptic release of glutamate for the NMDA receptor channel to open and permit the entry of both Na^+ and Ca^{2+} (Nowak *et al.* 1984) (see Figure 2-15). Furthermore, given their high Ca^{2+} permeability, NMDA receptors induce long-lasting alterations in synaptic strength and are required for classical LTP.

Given the prominent role of NMDA signaling in cellular memory (LTP), this receptor has been proposed as a potential therapeutic target for Alzheimer's disease. Indeed, one of the five prescription drugs approved by the FDA to treat the symptoms of Alzheimer's disease is memantine, an

NMDA receptor antagonist. Given that NMDA receptor antagonists block LTP and impair memory, it might seem counterintuitive that these drugs are used in Alzheimer's disease. However, memantine is a low-affinity, voltage-dependent, noncompetitive antagonist of NMDA receptors with fast on/off kinetics that inhibits excessive calcium influx induced by chronic overstimulation of the NMDA receptor. These unique pharmacological properties mean that memantine can inhibit pathological alterations in NMDA receptor function while preserving normal physiological activity. Maintenance of physiological activity is essential to protect against the negative effects on learning and memory observed with high-affinity NMDA receptor antagonists (Reisberg *et al.* 2003).

In addition to their effects on learning and memory, NMDA receptor antagonists also possess hallucinogenic properties. The hallucinogens phencyclidine and ketamine bind within the channel pore as noncompetitive receptor antagonists to inhibit NMDA receptor channel function. Moreover, in clinical studies, ketamine has been shown to induce schizophrenia-like symptoms in healthy people and to induce psychosis in schizophrenic patients. This psychotomimetic effect of NMDA receptor antagonists led to the NDMA hypothesis of schizophrenia, which posits that decreases in NMDA receptor function contribute to the pathophysiology of the disorder (Goff and Coyle 2001). This hypothesis is further supported by the observation that individuals with autoimmune antibodies to the NMDA receptor (anti-NMDA receptor encephalitis) display psychosis. This NMDA receptor hypofunction hypothesis suggests novel targets for therapeutic interventions for patients with schizophrenia. Therapeutic targets that augment NMDA receptor function are largely compounds that target the glycine co-agonist site. Direct glycine site agonists include glycine, D-serine, and D-cycloserine; indirect agonists include agents that block glycine degradation (D-amino acid oxidase [DAAO] inhibitors) or glycine uptake (glycine transporter-1 [GlyT-1] blockers). Unfortunately, the NMDA receptor-modulating drugs showed only small to moderate effects in treating negative symptoms and did not improve cognition in patients with schizophrenia (Buchanan *et al.* 2007).

Drugs used to treat major depressive disorder are moderately effective (effect sizes of 0.4-0.5), and most target noradrenergic and/or serotonergic neurotransmission (see sections on serotonin and norepinephrine transporters in this chapter). Furthermore, approximately 15%-25% of patients treated with such drugs have essentially no response and are considered to have treatment-resistant depression (TRD) (Nemeroff 2007). This high incidence of TRD has led to an examination of whether drugs that target different neuronal systems might be more effective, act faster, and/or be more useful in treating depression compared with current antidepressant drugs that target only monoamine neurotransmission. The "glutamate theory" of depression led to the suggestion that NMDA receptor antagonists may represent a novel therapeutic target for treatment. Preclinical studies have consistently demonstrated the efficacy of NMDA receptor antagonists in behavioral models with predictive validity of an antidepressant response. Further evidence supporting NMDA receptor antagonists as a therapeutic approach to depression was obtained in 2000, when ketamine, an NMDA receptor antagonist, was found in an open study to produce an antidepressant effect when administered to depressed patients (at subanesthetic doses) (Berman *et al.* 2000). Subsequent randomized double-blind studies also demonstrated a rapid antidepressant effect of ketamine, with high response rates even in patients with TRD. The efficacy in clinical trials led to FDA approval of the *S*(+)-enantiomer of ketamine, esketamine (sold under the brand name Spravato), for use in TRD. Given its rapid antidepressant action, esketamine was subsequently examined as a potential therapy for patients with suicidal ideation, and in 2020 esketamine was approved for use in the short-term treatment of suicidal thoughts. It should be noted that there are serious drawbacks to the use of this drug. Because of its potential to produce transient blood pressure and heart rate changes, esketamine is available only through a restricted program (U.S. Food and Drug Administration 2022). It can be dispensed only in health care settings that have been certified by this program, and only to patients who are enrolled in the program. Finally, doses must be administered under controlled conditions, with the patient being directly observed by a health care provider and monitored for at least 2 hours after administration. In addition to its effects on blood pressure and heart rate, esketamine can produce acute psychotomimetic effects, including hallucinations and dissociative effects. These effects, as well as ketamine's reinforcing properties, contribute to its abuse potential, which further complicates its use for the treatment of depression. Consequently, a significant amount of research is being examined to identify drugs that produce ketamine's beneficial clinical effects without also producing adverse effects.

Metabotropic glutamate receptors. The discovery of metabotropic glutamate receptors (mGluRs) drastically altered the traditional view of glutamatergic neurotransmission as mediating fast synaptic neurotransmission. Indeed, mGluRs can modulate fast glutamatergic signaling in a manner previously associated with monoamines and other neuromodulators. Thus, mGluRs provide a mechanism by which glutamate can modulate or fine-tune activity at the same synapses at which it elicits fast synaptic responses. The mGluRs are GPCRs, of which eight subtypes have been cloned, with multiple splice variants that are differentially expressed in distinct cell types throughout the CNS. These eight subtypes have been categorized into three subgroups (groups I, II, and III) largely based on the signaling transduction pathways that they activate (Table 2-4). Group I includes mGluRs 1 and 5, Group II includes mGluRs 2 and 3, and Group III includes mGluRs 4, 6, 7, and 8 (Niswender and Conn 2010).

Group I mGluRs. Group I mGluRs (which include mGlu1 and mGlu5 receptors) couple to G_q/G_{11} and activate PLC, resulting in generation of IP_3

and diacylglycerol. Thus, receptor stimulation leads to mobilization of intracellular calcium and activation of PKC. Group I mGluRs are often localized postsynaptically, and their activation leads to cell depolarization and increases in neuronal excitability. mGlu1 receptors are concentrated in perisynaptic and extrasynaptic areas, whereas mGlu5 receptors appear synaptic, functionally interacting with NMDA receptors in the postsynaptic density. Given their interaction with NMDA receptors, mGlu5 receptors have been associated with learning and memory. Indeed, mGluR5 knockout mice show memory impairments on specific behavioral tasks and reduced plasticity in the hippocampus. Whereas AMPA receptor signaling appears normal in these mice, NMDA receptor-mediated LTP is attenuated (Jia *et al.* 1998). Research on allosteric modulators for the mGluR5 receptor has yielded several compounds with potential clinical utility. PAMs may have utility for the treatment of cognitive deficits, including those seen in schizophrenia. Indeed, given that mGluR5 PAMs display robust antipsychotic-like effects and improve cognitive function in animal models, they may possess utility as novel antipsychotic and cognition-enhancing agents. In addition to the potential utility of mGluR5 PAMs in treating psychiatric disorders, NAMs or antagonists have been developed for the treatment of anxiety disorders and fragile X syndrome (FXS). Aberrant amygdala excitability has been linked to anxiety disorders, and attenuation of glutamatergic transmission (by decreasing mGluR5 activity) has been demonstrated to produce anxiolytic effects in rodent models. The proposed interaction between mGluR5 and FXS, a genetic condition that causes a range of developmental problems including intellectual developmental disorder, is based on the finding that the lack of fragile X mental retardation protein (FMRP) results in excessive glutamatergic signaling

via mGluR5 (Dolen *et al.* 2007). Thus, mGluR5 NAMs may represent a novel therapy for FSX. This hypothesis is supported by findings from preclinical research and clinical trials with the selective mGluR5 NAM fenobam (Berry-Kravis *et al.* 2009). Fenobam was developed in the 1970s as an anxiolytic; however, dose-limiting effects on memory decreased its utility. A pilot clinical study did not find major safety concerns with fenobam in FXS and suggested potential clinical improvements after a single dose that warrant further investigation (Berry-Kravis *et al.* 2009).

Group II mGluRs. Group II mGluRs include mGlu2 and mGlu3 receptors and are characterized as inhibiting adenylyl cyclase, but like many G_i-coupled receptors, they also regulate ion channel function. These receptors are largely presynaptic and negatively modulate glutamate and GABA neurotransmission. As detailed above (see "Group I mGluRs"), aberrant activity in the amygdala is associated with anxiety; thus, decreasing glutamatergic transmission in this region would likely produce an anxiolytic effect. This idea led to the development of group II selective mGlu2/3 receptor agonists that displayed robust anxiolytic effects in preclinical models. However, the efficacy of benzodiazepines for anxiety and the side effects associated with early mGlu2/3 receptor agonists limited the investigation of Group II mGluRs as anxiolytics. The hypothesis that aberrant glutamatergic signaling may also contribute to the symptoms of schizophrenia led to the development of pomaglumetad (LY-404039) and its prodrug (LY2140023) as potential antipsychotics. An initial Phase II clinical trial showed that LY2140023, taken twice daily for 4 weeks, improved schizophrenia symptoms, and the drug was heralded as a breakthrough, being potentially the first nondopaminergic antipsychotic (Patil *et al.* 2007). Unfortunately, development of LY2140023 as a treatment for schizophrenia was discontinued in 2012, when later studies found that its antipsychotic effect did not separate from placebo (Kinon *et al.* 2011). However, this compound was licensed to another pharmaceutical company, which reported that a meaningful subset of patients showed significantly improved outcomes; the company plans to utilize genetic biomarkers as a companion diagnostic to screen for appropriate patient subsets in future clinical trials of antipsychotic efficacy (see www.denovobiopharma.com).

Group III mGluRs. Group III mGluRs include mGlu4, mGlu6, and mGlu7 receptors and are similar to group II mGluRs in that they are coupled predominantly to $G_{i/o}$ proteins, leading to inhibition of adenylyl cyclase and regulation of ion channel function. Preclinical studies suggest that group III mGluRs are largely located presynaptically and decrease neurotransmitter release. Group III mGluRs are highly expressed throughout the basal ganglia, and the mGlu4 subtype is highly localized at striatopallidal synapses. This localization within the basal ganglia has led to the suggestion that group III mGluR agonists (or PAMs) might be effective in treating Parkinson's disease (Amalric *et al.* 2013). Activation of mGlu4 receptors reduces aberrant GABAergic transmission at the striatopallidal synapses in patients with Parkinson's disease. Furthermore, highly selective mGluR4 PAMs, such as PHCCC (*N*-phenyl-7-(hydroxyimino)cyclopropa[*b*]chromen-1a-carboxamide), display robust antiparkinsonian effects in rodent models. In addition, activation of mGlu4 receptors has also been shown to be neuroprotective in animal models of Parkinson's disease, a finding that suggests additional benefits for this class of compound (Amalric *et al.* 2013).

Glutamatergic (excitatory amino acid) transporters. As discussed earlier (see "Glutamatergic System"), glutamate transporters, also commonly known as excitatory amino acid transporters (EAATs), are the primary mechanisms terminating glutamatergic neurotransmission. Located pre-and postsynaptically as well as on astrocytes, glutamate transporters are essential for the rapid removal of synaptic and extracellular glutamate, thereby exerting tight control over glutamatergic neurotransmission and preventing neuronal death due to excitotoxicity (Lipton 1999). As is the case for the SLC6 family of transporters, EAATs use the free energy of ion gradients to carry glutamate into cells. In general, mammalian EAATs carry one glutamate molecule along with three sodium ions and one proton into the cytoplasm. There are five EAAT isoforms belonging to the solute carrier 1 (SLC1) family. EAAT1 (SLC1A3; also known as GLAST-1 [GLutamate ASpartate Transporter 1]) and EAAT2 (SLC1A2; also known as GLT-1 [GLutamate Transporter 1]) are located predominantly on astrocytes. EAAT1 is richly expressed in cerebellum, whereas EAAT2 is more diffusely expressed in the brain but is especially dense in hippocampus. EAAT3 (SLC1A1) and EAAT4 (SLC1A6) are located exclusively on neurons. EAAT4 is expressed in cerebellar Purkinje neurons, whereas EAAT5 (SLC1A7) is found only on neurons and Muller cells in the retina.

EAAT2 and EAAT1 reportedly make up 80% and 20% of cell-surface EAATs in the hippocampus, respectively (Holmseth *et al.* 2012), and EAAT2 mediates more than 90% of glutamate uptake in the CNS (Furness *et al.* 2008). EAAT2 and EAAT1 are also critical for normal brain development (Matsugami *et al.* 2006). Because of these important roles in CNS function, EAAT2, and to a lesser extent EAAT1, has been implicated in psychiatric disorders, including substance use disorders. (For comprehensive reviews of glutamate transporter structure, function, and regulation, see Jiang and Amara 2011, Sery *et al.* 2015, and Ryan *et al.* 2021.)

Dysfunction of glutamatergic signaling as well as glial dysfunction are thought to be involved in the etiologies of psychiatric disorders such as depression and schizophrenia (Nakagawa and Kaneko 2013). EAAT2 and EAAT1 have therefore been proposed as targets for novel therapeutics to treat these disorders. In general, EAAT2 and EAAT1 appear to be reduced in patients with depression or schizophrenia; mood stabilizers, such as sodium valproate, and antidepressants, such as fluoxetine (an SSRI) and tranylcypromine (an MAOI), can restore expression of these transporters. However, it is important to keep in mind that postmortem changes associated with patient demographics, long-term medication use, and suicide must be taken into account when considering these findings (for a review, see Parkin *et al.* 2018). A systematic review of the literature by Blacker *et al.* (2020) found that EAAT2 expression was decreased by chronic stress and that inhibition of EAAT2 promoted depressive-like behaviors in rodents. Consistent with findings in rodent studies, depression in humans has been associated with decreased EAAT2. Numerous gene variants for EAAT2 and EAAT1 have been identified (e.g., Poletti *et al.* 2018, 2019; Veldic *et al.* 2019), with some evidence pointing to associations with certain depression subtypes, schizophrenia, and deficits in cognitive function, memory, and executive function, as well as associations with suicide and response to drugs (for a review, see Blacker *et al.* 2020). A wide range of abused drugs, including amphetamines, cannabinoids, cocaine, ethanol, opioids, and nicotine, reduce EAAT2 expression and glutamate uptake. A number of preclinical and clinical studies (reviewed by Roberts-Wolfe and Kalivas 2015) have shown that pharmacological restoration of EAAT2 expression and function with *N*-acetylcysteine (a precursor to glutathione that is used to treat acetaminophen overdose) or ceftriaxone (a b-lactam antibiotic) may be a promising strategy for treating patients with a substance use disorder.

Finally, a less-studied transporter, the cystine/glutamate antiporter (also known as system $x_c^{[?]}$), is responsible for release of glutamate primarily from non-neuronal cells, thereby contributing to glutamate receptor activation. The cysteine/glutamate antiporter has been implicated in substance use disorders, schizophrenia, and neurodegenerative disorders, making it a putative novel target for therapeutic interventions (reviewed in Bridges *et al.* 2012).

Glycine

Glycine is a nonessential amino acid (see Figure 2-1) neurotransmitter in the CNS, serving as a co-agonist for NMDA receptor activation as well as an agonist at the glycine receptor, predominantly in the brain stem and spinal cord. Glycine may be produced in the CNS through a number of pathways; however, the most prominent is the synthesis of glycine from serine by the mitochondrial isoform of the enzyme serine hydroxymethyltransferase. Glycine is found in higher concentrations in the spinal cord than in the rest of the CNS, and it acts as an inhibitory neurotransmitter. Found in the seeds of the strychnine tree (*Strychnos nux-vomica*), strychnine is a highly toxic glycine receptor antagonist that can induce severe muscle rigidity and spasm, leading to respiratory failure and death. As discussed earlier (see "NMDA receptors"), glycine is critical for NMDA receptor channel opening; however, this effect is strychnine-insensitive, which suggests that glycine's actions on NMDA receptor function are different from its actions in the spinal cord, where glycine's inhibitory effect is blocked by strychnine. Indeed, glycine receptors have been cloned and have been demonstrated to be ionotropic receptors that generally produce effects via Cl[?]-mediated hyperpolarization.

Glycine Receptors

Receptors of the glycine family are tetramers, arranged as five subunits, with four known isoforms of the a subunit (a1-4) and a single b subunit. Each heteromeric receptor is thought to contain either three a subunits and two b subunits or four a subunits and one b subunit. Given the localization of glycine receptors within the spinal cord, it is perhaps not surprising that most research to date has focused on developing glycine receptor-targeted treatments for chronic pain. Although it is evident that glycine receptors are present on motoneurons, identification of the a3 subunit in sensory divisions of the spinal cord involved in pain processing has led to increased research efforts targeting a3-containing glycine receptors (Harvey *et al.* 2009). Development of glycine receptor a3 subunit knockout mice has permitted investigation of the effects of glycine in the absence of subtype-selective ligands. Notably, the a3-containing glycine receptors appear to play a central role in inflammatory pain while being less relevant to other pain states (e.g., neuropathic pain) (Harvey *et al.* 2009).

Glycine Transporters

Two subtypes of glycine transporter, GLYT1 and GLYT2, clear glycine from synapses and extracellular fluid. GLYT1 is found predominantly on astrocytes but also on neuronal elements including glutamatergic terminals and postsynaptic membranes. In contrast, GLYT2 is found exclusively on presynaptic glycinergic terminals. GLYT1 is widely expressed in the brain but is most dense in the cerebellum, substantia nigra, brain stem, cortex, and hippocampus. GLYT2 is expressed predominantly in the cerebellum and brain stem (Cubelos *et al.* 2005; Zafra *et al.* 1995). Glycine taken up into nerve terminals is repackaged into vesicles by the vesicular inhibitory amino acid transporter (VIAAT), also known as the vesicular GABA transporter (vGAT). Because glycine and GABA share this vesicular transporter, both neurotransmitters can be released from the same vesicles. GLYT1 and GLYT2 can be pharmacologically distinguished by *N*-

methylglycine (sarcosine), which inhibits GLYT1 but not GLYT2. These two glycine transporter subtypes belong to the SLC6 family and are encoded by the genes *SLC6A9* and *SLC6A5*. Like other members of the SLC6 family, glycine transporters use the free energy created by the sodium gradient maintained by the plasma membrane Na$^+$/K$^+$ ATPase to transport glycine molecules into the cytosolic compartment. (For comprehensive reviews of glycine transporter structure, function, and regulation, see Kristensen *et al.* 2011 and Zafra *et al.* 2008.)

Both glycine transporters have been linked to the etiology and/or the treatment of a number of psychiatric disorders, including schizophrenia, depression, OCD, and neurocognitive disorders, as well as to alcohol use disorder, epilepsy, pain, breathing disorders, and hyperekplexia (a startle disease) (for a review, see Harvey and Yee 2013). Interestingly, several mutations in the gene encoding GLYT2 have been identified in patients with hyperekplexia, a rare hereditary neurological disorder that may affect infants (either as newborns [neonatal] or prior to birth [in utero]) as well as children and adults. Individuals with this disorder have an excessive startle reaction (eye blinking or body spasms) to sudden, unexpected noise, movement, or touch. Most mutations were loss-of-function mutations (Eulenburg *et al.* 2006; Rees *et al.* 2006). Subsequent studies have provided evidence that loss-of-function (or damaging) GLYT1 gene variants may afford protection against schizophrenia, although further studies are needed to confirm these initial findings (Curtis 2020). Of the two transporter types, GLYT2 has garnered the most attention as a potential target for the treatment of pain, although GLYT1 also appears to be a putative target for pain, as well as for a number of the above-mentioned pathologies (Harvey and Yee 2013). Prominent among these, GLYT1 is under active investigation for the treatment of schizophrenia (Cioffi 2018; Cioffi and Guzzo 2016; Singer *et al.* 2015). Despite the promise of GLYT1 inhibitors as therapeutics for schizophrenia and related psychiatric disorders, no compounds have gone further than Phase III clinical trials at this time.

GABAergic System

GABA is the primary inhibitory amino acid neurotransmitter (see Figure 2-1) in the mammalian CNS and, as is the case for glutamate, is present in high concentrations throughout the brain. GABA is responsible for inhibitory neurotransmission via activity at both ionotropic and metabotropic GABA receptors. An imbalance between excitatory and inhibitory transmission contributes to the pathophysiology of a number of psychiatric disorders, including autism spectrum disorder and schizophrenia (Sohal and Rubenstein 2019).

GABA shares the same complex and compartmentalized biosynthetic pathway as glutamate, where glutamine is synthesized and transported from astrocytes to neurons via a sodium-coupled neutral amino acid transporter. In neurons, the enzyme glutaminase converts glutamine to glutamate, which is then converted to GABA by the enzyme glutamic acid decarboxylase (GAD). GAD exists in two isoforms, GAD67 and GAD65 (named for their molecular weights), which are encoded by distinct genes (*GAD1* and *GAD2*). GABA is packaged for release by vesicular GABA transporters. In common with the other amino acid transmitters, GABA's actions are terminated by high-affinity Na^+-dependent excitatory amino acid transporters found in neurons and glia. Neuronal uptake permits immediate repackaging of GABA into vesicles for release. Within astrocytes, GABA is first converted back into glutamate by the enzyme GABA transaminase (GABA-T) via a pathway known as the "GABA shunt." Glutamate is then converted to glutamine by the enzyme glutamine synthase, and glutamine diffuses back into the neuron, completing the cycle (Figure 2-16).

See Plate 14 to view this figure in color.

GABA is synthesized from glutamate by the enzyme glutamic acid decarboxylase (GAD) and, following release, binds to both ionotropic GABA_A and metabotropic GABA_B receptors. GABA_A receptors are ligand-gated $\text{Cl}^{[?]}$ channels that hyperpolarize the cell and mediate fast inhibitory signaling in the brain. $GABA_A$ receptors are heteropentameric receptor complexes, composed of numerous subunit isoforms that determine agonist affinity, allosteric modulation, and other channel properties. Note that GABA transporters are located both synaptically (as shown in figure) and extrasynaptically. AC = adenylyl cyclase; cAMP = cyclic adenosine monophosphate; GABA-T = GABA transaminase; GAT = GABA transporter; TBPS = *t*-butylbicyclophosphorothionate; VGAT = vesicular GABA transporter.

In the brain, GABAergic neurons display robust heterogeneity, with numerous subpopulations distinguished by a combination of morphological, physiological, and molecular characteristics. Within cortical microcircuits, these GABA neuron subtypes differentially regulate excitatory/inhibitory transmission. Two subclasses of GABA neurons that have gained significant attention for their potential role in psychiatric disorders are the parvalbumin-containing interneurons and the somatostatin-containing interneurons, both of which have been found to be selectively decreased in the brains of patients with schizophrenia, autism spectrum disorder, or Alzheimer's disease. These interneuron populations are distinct in terms of both anatomy and neurophysiology (Lewis *et al.* 2005). For example, parvalbumin-containing neurons display a fast firing pattern and synapse on the soma and initial segment, which makes them well situated to regulate phasic pyramidal cell output. By contrast, somatostatin-containing

neurons display a slow firing pattern and synapse on more distal dendrites of the pyramidal neuron, where they play a more modulatory role. Interestingly, parvalbumin and somatostatin interneurons share a similar developmental trajectory from common precursors in the embryonic medial ganglionic eminence, which may explain why developmental disorders such as schizophrenia display selective decreases in these interneurons. A decrease in interneuron function is thought to contribute to the aberrant cortical and hippocampal activity associated with specific symptom domains in patients with schizophrenia.

GABA Receptors

GABA receptors in the CNS can be classified into two major subtypes: ligand-gated ion channel (ionotropic) receptors and G protein-coupled (metabotropic) receptors.

Ionotropic GABA receptors. The ionotropic GABA receptors (see Figure 2-16) mediate fast inhibitory neuronal transmission in the CNS. The $GABA_A$ receptor is the more prevalent of the GABA receptors and, as a result, has been extensively studied and characterized. Structurally, $GABA_A$ receptors are members of the superfamily of pentameric ligand-gated ion channels, which also include nicotinic ACh receptors, serotonin type 3 ($5\text{-}HT_3$) receptors, and glycine receptors and which differ from the tetrameric ionotropic glutamate receptors. The $GABA_A$ receptor is a ligand-gated $Cl^{[?]}$ channel that generally produces effects via $Cl^{[?]}$-mediated hyperpolarization of the neuron (see Figure 2-16). This receptor is a heteropentameric complex composed of numerous subunit isoforms that determine agonist affinity, allosteric modulation, and other channel properties. The $GABA_A$ receptor shows enormous heterogeneity, being composed of a combination of at least 19 cloned subunits in designated subunit families (a1-6, b1-3, g1-3, d, e, th, p, and r1-3) (Sigel and Steinmann 2012). The most common $GABA_A$ receptors typically exist as a pentamer composed of two a subunits, two b subunits, and a g subunit (a2b2g), although considerable diversity exists. For example, substitution of the g subunit with a d subunit causes the receptor to be localized extrasynaptically, where it plays a larger role in the regulation of tonic neuronal activity. In addition, three r subunits have been cloned that do not appear to assemble with other subunits; instead, r subunits homo-oligomerize to form the $GABA_A$-r receptor (previously referred to as the $GABA_C$ receptor), which is highly expressed in the retina. This enormous receptor heterogeneity supports the complex, finely tuned role that inhibitory neurotransmission plays in brain function (Sigel and Steinmann 2012).

As a ligand-gated ion channel, the $GABA_A$ receptor requires two molecules of GABA to bind to the orthosteric site located at the interface between the a and b subunits. Ligand binding produces a conformational change leading to opening of the $Cl^{[?]}$ channel and neuronal inhibition driven via $Cl^{[?]}$-mediated hyperpolarization of the neuron. It should be noted that the pore permits bidirectional flow of $Cl^{[?]}$ ions, and the inhibitory effects of GABA are due to the $Cl^{[?]}$ concentration gradient, with high levels in the extracellular space relative to the cytoplasm. The $Cl^{[?]}$ concentration gradient is controlled and regulated by the K^+-$Cl^{[?]}$ co-transporter, KCC2, which maintains the intracellular $Cl^{[?]}$ concentration below its electrochemical equilibrium potential. KCC2 utilizes the K^+ gradient generated by the Na^+/K^+ ATPase to drive chloride from neurons. Interestingly, KCC2 expression is low during mammalian embryogenesis, a time when complex neural networks are forming and undergoing extensive remodeling (Rivera *et al.* 1999). By contrast, immature neurons express relatively high levels of NKCC1, a Na^+-K^+-$2Cl^{[?]}$ co-transporter that uses the electrochemical gradient of Na^+ (again, generated by the Na^+/K^+ ATPase) to transport Na^+, K^+, and $Cl^{[?]}$ into the cell. As long as NKCC1 transporters are expressed at sufficient levels, internal $Cl^{[?]}$ concentrations in neurons will be high, producing an outward driving force; therefore, $GABA_A$ channel opening causes $Cl^{[?]}$ to leave the cell and the membrane to depolarize. Thus, GABA can be either excitatory or inhibitory, depending on the relative intracellular concentration of $Cl^{[?]}$, which is high during early neuronal development (due to high NKCC1 expression) and low in mature neurons (due to KCC2 expression) (Rivera *et al.* 1999).

Given the enormous heterogeneity of the $GABA_A$ receptor, it is perhaps not surprising that numerous sites exist for allosteric modulation. Indeed, endogenous neurosteroids, such as allopregnanolone (a metabolite of progesterone), are known allosteric modulators of the $GABA_A$ receptor. Allopregnanolone (also known as brexanolone and marketed under the brand name Zulresso) was the first therapeutic to be approved by the FDA specifically for the treatment of postpartum depression. Furthermore, allopregnanolone is one of only two recently approved fast-acting antidepressants, with ketamine being the other (see "NMDA receptors" under "Ionotropic glutamate receptors" in the section "Glutamatergic Receptors"). Allopregnanolone readily crosses the blood-brain barrier and acts as a positive allosteric modulator at the $GABA_A$ receptor. Allosteric modulators act either as PAMs (which enhance Cl[?] currents through $GABA_A$ receptors to augment inhibitory signals) or as NAMs, or inverse agonists (which decrease Cl[?] flow through the pore of the receptor).

It is now well established that benzodiazepines, some of the most widely used psychotherapeutic drugs for the treatment of anxiety and sleep, function as PAMs by binding to an allosteric site on the $GABA_A$ receptor located at the interface between the a and g subunits (notably, g subunits are required for benzodiazepine binding and sensitivity). As PAMs, benzodiazepines increase the amplitude and frequency of inhibitory postsynaptic currents in response to GABA binding. It should be noted that $GABA_A$ receptors are widely distributed throughout the brain, and benzodiazepines target the majority of these synaptic receptors. For this reason, benzodiazepines are CNS depressants and produce side effects such as sedation, memory problems, and confusion.The extensive heterogeneity of $GABA_A$ receptors has prompted considerable research investigating whether the desirable and undesirable effects of benzodiazepines might be differentiated on the basis of the presence or absence of different subunit compositions (Olsen and Sieghart 2008). Given that the benzodiazepine binding site is located at the interface between the a and g subunits, and that there are six distinct a subunits, genetic knockouts have been used to examine the respective contributions of these subunits to the behavioral effects of benzodiazepines. Data from these genetic knockout studies indicate that a1-containing $GABA_A$ receptors mediate the sedative effects of benzodiazepines, whereas the a2-and/or a3-containing receptors mediate the anxiolytic effects (Atack 2005). For this reason, pharmaceutical companies have attempted to develop subunit-selective compounds capable of modulating a2/a3 but not a1 receptor function, in the hope that such compounds would be nonsedating anxiolytics. The investigational agent TPA-023 (MK-0777) was developed as a subunit-selective partial agonist at the a2 and a3 GABA_A receptor subunits. As predicted, it produced anxiolytic effects without sedative effects in animal models (Atack *et al.* 2006). In human trials, TPA-023 showed efficacy comparable to that of prototypic benzodiazepines but had fewer side effects (de Haas *et al.* 2007). Unfortunately, development of this compound for clinical use was discontinued because of toxic effects (cataracts); however, the premise of a2/a3-selective benzodiazepines for the treatment of anxiety appears promising.

Increased attention has been given to the relatively minor a5 subunit due to its enrichment throughout the hippocampus, where it accounts for approximately 20% of benzodiazepine binding sites. Thus, a5 subunit-selective PAMs and NAMs may be able to preferentially regulate hippocampal function following systemic administration. Clinical and preclinical research has identified augmented hippocampal activity as a key pathology contributing to schizophrenia (Lodge and Grace 2011). It is therefore possible that a5 subunit-selective PAMs may decrease aberrant hippocampal function and treat schizophrenia without producing the side effects associated with conventional D_2 receptor antagonist antipsychotics. Indeed, preclinical studies suggest that a5 subunit-selective PAMs are effective in reducing aberrant neurophysiological activity in models used to study schizophrenia (Gill *et al.* 2011). In addition, the hippocampus has been identified as a potential target for therapeutic intervention in depression, and novel a5 subunit-selective PAMs and NAMs have been developed that show antidepressant efficacy in rodent models (Carreno *et al.* 2017).

Metabotropic GABA receptors. The metabotropic GABA_B receptors are GPCRs assembled as heterodimers from two subunits of the receptor (GABA_{B1} and GABA_{B2}). Whereas GABA_A receptors mediate fast inhibitory signaling, activation of $GABA_B$ receptors produces a slower, more prolonged inhibition. These receptors not only are localized postsynaptically but also are found presynaptically on both GABA and glutamate neurons, where GABA spillover from local inhibitory synapses may readily activate $GABA_B$ receptors in a dynamic, state-dependent manner. Activation of $GABA_B$ receptors results in slow inhibitory postsynaptic potentials that are mediated by G protein-activated K^+ channels (Kir3 channels, or GIRKs) as well as inhibition of neurotransmitter release through inhibition of voltage-gated Ca^{2+} channels. In the classical pathway, $GABA_B$ receptor activation results in opening of the GIRK channel via direct interaction with the Gbg subunit of the heterotrimeric $G_{i/o}$ family (Figure 2-17). This GPCR-GIRK interaction mediates the inhibitory action of many neurotransmitters, including acetylcholine, dopamine, serotonin, and others. In addition, $GABA_B$ receptors are coupled to G_i and G_o and generally inhibit adenylyl cyclase activity. $GABA_B$ receptors are class C GPCRs (as are metabotropic glutamate receptors) and prototypical heterodimers. There are two subunits of the receptor, $GABA_{B1}$ and $GABA_{B2}$, that assemble as heterodimers by linking intracellular C termini. It is thought that the $GABA_{B1}$ subunit contains the orthosteric binding site, whereas the $GABA_{B2}$ subunit couples to the G protein. Therefore, it is necessary for $GABA_B$ receptors to form heterodimers for GABA-mediated signaling (Bettler *et al.* 2004).

The metabotropic GABA$_B$ receptors are GPCRs assembled as heterodimers from two subunits of the receptor (GABA$_{B1}$ and GABA$_{B2}$) coupled to G$_{i/o}$. Activation of GABA$_B$ receptors inhibits adenylyl cyclase, decreasing cAMP production. In addition, the Gbg subunit directly activates G protein-activated K^+ channels and inhibits voltage-gated Ca^{2+} channels, resulting in neuronal inhibition. Baclofen, an analog of GABA first synthesized in the 1960s as a selective GABA$_B$ agonist, is the only FDA-approved selective GABA$_B$ receptor agonist. Sold under the brand name Lioresal, baclofen is used primarily in the treatment of spastic movement disorders associated with spinal cord injury or multiple sclerosis. Interestingly, baclofen analogs that block slow inhibitory signaling (i.e., GABA$_B$ antagonists) have been developed. Several of these GABA$_B$ receptor antagonists have been found to improve cognitive performance in a variety of animal models (Bowery 2006). Furthermore, when CGP36742, a selective brain-penetrant GABA$_B$ receptor antagonist, was investigated in a double-blind, placebo-controlled study, it appeared to be well tolerated and produced significant improvements in working memory, psychomotor speed, and attention in patients with mild cognitive impairment (Froestl *et al.* 2004). Whether GABA$_B$ receptor antagonists have clinical utility in treating cognitive impairment in patients with dementia remains to be evaluated fully.

GABA Transporters

Four subtypes of GABA transporters (GATs)--GAT1, GAT2, GAT3, and the betaine GAT (BGT1)--clear GABA from synapses and extracellular fluid. GAT1 and GAT3 are responsible for the majority of GABA clearance in the CNS. GAT1 is located in GABAergic axon terminals, astrocytes, oligodendrocytes, and microglia (Fattorini *et al.* 2020) and is densely expressed in the hippocampus and cerebellum, predominantly in the perisynaptic region of presynaptic boutons. However, GAT1 expression is more than threefold higher in astrocytic membranes than in axon terminals. GAT3 is located in brain stem and cortical neurons and is found predominantly on astrocytes (for a review, see Ryan *et al.* 2021). GATs belong to the SLC6 family. GAT1 is encoded by *SLC6A1* and GAT3 by *SLC6A11*. As is the case for other members of the SLC6 family, GATs use the concentration gradient of sodium (generated by the plasma membrane Na$^+$/K$^+$ ATPase) as the driving force to carry GABA across the plasma membrane into the cytosolic compartment. Once inside the cell, GABA is repackaged into vesicles by

VGAT. Like other members of the SLC6 family, GATs are tightly regulated by numerous endogenous and exogenous factors. Most studies of GABA transporters have focused on GAT1 and show that its uptake capacity and membrane expression are controlled by numerous kinases, phosphatases, SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein [SNAp] REceptors) complexes, growth factors, and auto-and heteroreceptors, as well as by GAT1 inhibitors. (For comprehensive reviews of GAT structure, function, and regulation, see Kristensen *et al.* 2011, Ryan *et al.* 2021, and Soudijn and van Wijngaarden 2000.)

Gene variants of GAT1, the majority of which are loss-of-function mutations, are associated with neurodevelopmental disorders such as intellectual developmental disorder (intellectual disability), autism spectrum disorder, and epilepsy (Bhat *et al.* 2021; Goodspeed *et al.* 2020), as well as with psychiatric disorders including anxiety disorders and schizophrenia (Rees *et al.* 2020; Thoeringer *et al.* 2009). GAT1 inhibitors, such as tiagabine, are used for treatment of epilepsy and have also been shown to be effective in the treatment of pain (Todorov *et al.* 2005; Zafar and Jabeen 2018). In clinical trials, tiagabine is being investigated for other indications, including as a treatment for cognitive deficits in schizophrenia (Xu and Wong 2018). Preclinical studies showed that tiagabine and other GAT1 inhibitors possess antinociceptve, antiallodynic, and anxiolytic properties, and these findings have encouraged further investigation of GAT1 inhibitors as therapeutics for a range of disorders (Ryan *et al.* 2021). Because of the prominent role of GAT1 (relative to other GATs) in CNS regulation of GABA uptake, development of non-GAT1 selective inhibitors has lagged behind development of selective GAT1 inhibitors. Consequently, less is understood about the therapeutic potential of GAT2, GAT3, and BGT1 (Sarup *et al.* 2003). It is known that GAT3 activity in astrocytes modulates excitatory neurotransmission in the hippocampus (Boddum *et al.* 2016). Accumulating pharmacological evidence indicates that GAT3, like GAT1, may be a promising target for treatment of numerous brain disorders (for reviews, see Damgaard *et al.* 2017 and Zareba *et al.* 2021).

Purinergic Transmission: Focus on Adenosine

The term *purinergic* was introduced by Burnstock in 1972 to describe transmission mediated by adenosine triphosphate (ATP), which is a purine by virtue of being a heterocyclic organic compound with two rings fused together (Burnstock 2014). As shown in Figure 2-1, adenosine (short for adenosine nucleoside) is also a purine. Adenosine is formed by the binding of adenine to D-ribose, making it a nucleoside. The original identification of adenosine was in 1929, when Drury and Szent-Gyorgyi extracted it from the mammalian heart (Drury and Szent-Gyorgyi 1929). It is now well established that adenosine has regulatory functions in organs such as the heart, kidney, lung, and gastrointestinal tract, and it is also known to play a role in respiratory and inflammatory diseases and in cancers (van Calker *et al.* 2019).

Our focus here, however, is on adenosine acting as a transmitter in the CNS. Adenosine is distributed widely in the brain. Even though adenosine does not meet all of the original criteria for a neurotransmitter mentioned at the beginning of this chapter, our expanding understanding of brain function validates its action as a neuromodulatory chemical that exerts both excitatory and inhibitory effects. Adenosine can be produced in three ways: 1) breakdown of ATP to adenosine diphosphate (ADP), followed by further breakdown to adenosine; 2) reaction of adenine with 1-phosphate ribose; and 3) hydrolysis of *S*-adenosyl-L-homocysteine to homocysteine and adenosine. Adenosine is released from both nerves and glia. Astrocytes are the main source of ATP released into synapses, from which it can be cleaved to adenosine (Boison 2010). Movement of adenosine across the plasma membrane is facilitated by bidirectional nucleoside transporters that either function passively or are active Na^+ transporters. Thus, the extracellular concentration of adenosine is regulated by its cellular release, its reuptake by transporters, and its conversion by enzymes on the cell surface (Effendi *et al.* 2020).

Purinergic receptors were first described in 1976. Two families of receptors were proposed: P_1 for adenosine and P_2 for ATP/ADP. The receptor for adenosine is now called the adenosine receptor, and there are four subtypes--A1, A2A, A2B, and A3--all of which have been cloned. The A1 and A2A receptors have higher affinity for adenosine than do either the A2B or the A3 receptor. Consequently, the A1 and A2A receptors are thought to be activated by normal physiological concentrations of adenosine, whereas the A2B and A3 receptors become activated when adenosine concentrations are elevated--as occurs, for example, in pathological conditions such as hypoxia (Burnstock 2014; Effendi *et al.* 2020). These four subtypes differ in their ligand-binding affinities, signaling mechanisms, and distribution in the brain. All four subtypes are GPCRs, with A1 and A3 receptors linked to G_i (so as to inhibit adenylyl cyclase) and A2A and A2B receptors linked to G_s (so as to stimulate adenylyl cyclase). A2B receptors stimulate not just adenylyl cyclase but also PLC. A3 receptors also stimulate PLC even though they inhibit adenylyl cyclase. A2A receptors can additionally be coupled to G_{olf} and activate PKA (Effendi *et al.* 2020; Liu *et al.* 2019; Figure 2-18).

See Plate 16 to view this figure in color.

Intracellular adenosine is produced via dephosphorylation from the main source, AMP, via both cN-I and cN-II and hydrolysis of *S*-adenosyl-homocysteine through the enzyme *S*-adenosyl-L-homocysteine hydrolase. The extracellular formation of adenosine is the result of enzymatic cascades consisting of ATP transport, hydrolysis of ATP and ADP by CD39 to form AMP, and dephosphorylation of AMP by CD73. Extracellular adenosine binds adenosine receptors (A_1AR, A_{2A}AR, A_{2B}AR, and A_3AR) on the surface of cells. Each adenosine receptor is a GPCR that transmits the signal from adenosine by stimulating or inhibiting cyclic AMP (cAMP). The A1 adenosine receptor has a widespread distribution in the brain and is found at its highest density in the cerebral cortex, thalamus, and lateral hypothalamus. The A2A receptor is found in brain areas rich in dopamine and is co-expressed with D_2 receptors on GABAergic striatopallidal neurons. The A2B receptor is found primarily in the CA_1 and CA_3 regions of the hippocampus. The A3 receptor is also widely distributed in the brain but is present at a much lower density than the A1 receptor (Liu *et al.* 2019).

Converging evidence indicates that adenosine plays a role in arousal and attention, given its hypnotic/sedative effects. Part of the evidence is the mild stimulant and alerting effects of methylxanthines, such as caffeine (coffee), theophylline (tea), and theobromine (cocoa), which are antagonists of A1 and A2A receptors. At higher doses, these substances can be anxiogenic and can even cause panic attacks, indicating a role for adenosine in anxiety (van Calker *et al.* 2019). Thus, agents selective for the various adenosine receptors may be useful in treating anxiety disorders. It has also been proposed that adenosine acts as a "retaliatory" substance to signal a disequilibrium between energy supply and demand so as to stimulate counterbalancing measures through activation of its various receptors (van Calker *et al.* 2019). Thus, for example, when production of ATP is reduced during hypoxia, adenosine accumulates and inhibits release of glutamate, which can be exocytotoxic.

Adenosine is the predominant presynaptic modulator of transmitter release in the brain. This occurs by its stimulation of presynaptic A1 receptors located on many different types of neurons (e.g., GABA, glutamate, dopamine, norepinephrine, 5-HT, ACh). Postsynaptic A1 receptors can inhibit signaling by causing hyperpolarization to reduce excitability. A2A receptors are present in both neurons and glia; in neurons, they are located on both presynaptic and postsynaptic neurons. Of current interest is the finding that A2A receptors can form heterodimers with other receptors, including the A1 receptor. Much attention has recently been focused on A2A/D_2 heterodimers. These heteromeric receptors have a pharmacology and function distinct from those of their constitutive receptors, and their possible role in schizophrenia and substance use disorders is an active area of research (Borroto-Escuela *et al.* 2020; Wydra *et al.* 2020). The A2A receptor itself may be involved in various effects of psychostimulants, nicotine, opioids, and ethanol, given that A2A receptor activation attenuates the rewarding effects of cocaine but not those of other psychostimulants. Such receptor stimulation also reduces opioid or alcohol withdrawal symptoms in laboratory animals (Wydra *et al.* 2020).

There is also an emerging literature examining the role of adenosine in depression and its treatment (Liu *et al.* 2019). For example, in rodents, antagonism of A2A receptors produces an antidepressant-like effect, whereas overexpression of these receptors causes depression-like behaviors, including anhedonia. By contrast, activation of A1 receptors produces an antidepressant-like effect (van Calker *et al.* 2019).

Peptidergic Neurotransmission

Neuromodulators encompass a variety of chemically different molecules that influence the activity and physiological and behavioral outcomes of classical neurotransmitters. Neuromodulators include adenine purines (e.g., ATP, nicotinamide adenine dinucleotide), endocannabinoids (e.g., 2-arachidonoylglycerol), neurotrophic factors (e.g., BDNF, fibroblast growth factor), gasotransmitters (e.g., nitric oxide, hydrogen sulfide), and neuropeptides. In this section we focus on general characteristics of peptidergic neuromodulators.

The idea that a peptide synthesized in neurons could be released and could act as a neurotransmitter was first introduced by the Dutch scientist David de Wied (De Wied and De Kloet 1987). Neuropeptide transmission differs from classical neurotransmission in several ways (Figure 2-19) (van den Pol 2012). Briefly, neuropeptides are synthesized as large precursor molecules (prepropeptides) in the cell body and dendrites, and the bioactive peptides are excised from the prepropeptides by convertase enzymes. After synthesis, neuropeptides are packed into large, dense-core storage vesicles (unlike the small vesicles in which nonpeptidergic neurotransmitters are stored) and are released by exocytosis from nerve terminals, dendrites, and soma. Release of neuropeptides generally is elicited by rapid-burst firing, prolonged depolarization, and elevated intracellular Ca^{2+}, and it often takes place in tandem with release of nonpeptidergic neurotransmitters (i.e., co-release). Unlike release of classical neurotransmitters, which occurs at the synaptic cleft of the active synapse, exocytosis of neuropeptides can occur at extrasynaptic sites along the neuronal membrane. Local diffusion ensures that signaling has a wide action range that includes the synaptic partner cell as well as both adjacent cells and remote sites (i.e., paracrine actions). Neuropeptides are not cleared by reuptake and recycling systems; instead, they are degraded by specific peptidases.

Most of the more than 100 different neuropeptides identified in the CNS act via one or more GPCRs. Hypothalamic neurons express large quantities of different neuropeptides (e.g., CRF, vasopressin, oxytocin, neuropeptide Y, somatostatin, leptin, ghrelin) that are important in regulating several homeostatic functions. However, neuropeptides are also present in other brain areas. For example, in the hippocampus, GABAergic interneurons have been shown to contain several neuropeptides, including neuropeptide Y, somatostatin, vasoactive intestinal polypeptide, cholecystokinin, dynorphin, enkephalin, neurokinin B, and substance P. Functionally, hippocampal neuropeptides may be involved in the regulation of neurotransmitter release (i.e., GABA and glutamate) at presynaptic terminals. Moreover, there is evidence that neuropeptides act as trophic factors for glial cells (van den Pol 2012).

Both preclinical and human postmortem studies show that dysregulation of neuropeptide signaling is associated with psychiatric conditions, but because of the different forms of receptors and associated signaling, identification of the specific effects of any one neuropeptide (or neurotransmitter) can be difficult. For example, galanin acting through receptors GalR1 and GalR3, which are GPCRs associated with G_i inhibitory

signaling, increases depressive-like behaviors, whereas galanin-dependent activation of GalR2 has anxiolytic effects and mediates resilience to stress (Hokfelt *et al.* 2018). Drugs targeting the galanin system, particularly GalR3 antagonists and GalR2 allosteric modulators, have been recently proposed as promising candidates for the treatment of depression and substance-related and addictive disorders (Genders *et al.* 2020; Hokfelt *et al.* 2018).

The role of brain gut peptides in mood disorders has also received considerable attention in recent years (Farzi *et al.* 2019; Lach *et al.* 2018; Rasmusson and Pineles 2018). Brain gut peptides (e.g., melatonin, ghrelin, substance P, cholecystokinin, neuropeptide Y) are involved in a number of homeostatic processes, including regulation of sleep, food intake, pain sensitivity, and inflammation. The neurobiology and pharmacology of this varied class of peptides is a current topic of intense research, as investigators and clinicians are acquiring a new appreciation of the impact of alterations in peripheral homeostasis in the etiology of psychiatric disorders.

In general, the role of neuropeptide systems in regulation of normal neurotransmitter function has been established in multiple preclinical studies, and therefore the idea of using these neuromodulators and their receptors as adjunctives to existing therapies has conceptually attracted increasing interest in recent years (Golyszny and Obuchowicz 2019). Space limitations prevent an extensive discussion of the neuropeptides known to exist in the mammalian brain; however, Table 2-5 highlights some of the major neuropeptides of potential psychiatric relevance. In the remainder of this section, we briefly discuss selected neuropeptide systems; for a more detailed discussion of neuropeptides as potential drug targets for psychiatric disorders, the interested reader is referred to recent comprehensive reviews of this emerging field of study (Abramova *et al.* 2020; Bali *et al.* 2014; Basu *et al.* 2021; Eiden *et al.* 2020; Gotter *et al.* 2012; Gupta and Prabhavalkar 2021).

TABLE 2-5. Selected peptides and their presumed relevance to psychiatric disorders and treatment

Group/peptide	Potential clinical relevance
Opioid and related peptides	
Endorphin	Analgesia for chronic pain
Enkephalin	Analgesia
Dynorphin	Analgesia
Nociceptin	Binds opioid-receptor-like 1 (ORL_1) receptor; increased pain perception
Gut-derived peptides	
Vasoactive intestinal peptide	Sexual behavior
Cholecystokinin	Anxiety/panic
Secretin	Anecdotal reports describing benefit in autism spectrum disorder and transient antipsychotic properties
Somatostatin	Mood disorders and treatment
Tachykinin peptides	

Group/peptide	Potential clinical relevance
Substance P (substance K)	Receptor is neurokinin-1 (NK_1); no efficacy shown for depression; inflammation
Neurotensin/neuromedin N	Analgesia, hypothermia; regulated by lithium; involved in dopamine signaling
Pituitary peptides	
Oxytocin	Affiliative, prosocial bonding behavior; decreases fear; may help increase sociability in autism spectrum disorder
Vasopressin	Also called antidiuretic hormone; receptors are V_{1A}, V_{1B}, and V_2; antagonists have anxiolytic, anti-aggression, and anti-irritability properties
Adrenocorticotropic hormone	Dysregulated in mood disorders
Melanocyte-stimulating hormone	Antidepressant and anti-anxiety properties
Hypothalamic-releasing factors	
Corticotropin-releasing factor	Anxiety and fear
Thyrotropin-releasing factor	Potential antidepressant effects
Others	
Calcitonin gene-related peptide	Regulated by electroconvulsive therapy and lithium
Angiotensin	Mood disorders, bipolar disorder
Leptin	Satiety signal; inhibits feeding drive
Cocaine-and amphetamine-related transcript	Substance use disorders, eating disorders

Group/peptide	**Potential clinical relevance**
Galanin	Potentially relevant for diagnosis of Alzheimer's disease and other neurocognitive disorders
Neuropeptide Y	Potential endogenous anxiolytic; regulated by antidepressants/lithium; reduced by early maternal separation; antagonists may decrease appetite
Orexin/hypocretin	Narcolepsy and other sleep abnormalities; eating disorders

Note. This table summarizes selected peptides and their presumed relevance for psychiatric disorders and their treatment; it is not meant to be an exhaustive listing of findings. It should also be noted that in some cases--for example, corticotropin-releasing factor (mood/anxiety), neuropeptide Y and neurotensin (regulation by medications), oxytocin (affiliative behavior), and orexin (narcolepsy)--data are quite convincing. In many other examples noted, the evidence must be considered preliminary but is promising and warrants further investigation. A discussion of these peptides is beyond the scope of this introductory chapter; nevertheless, readers are encouraged to explore the latest research in this rapidly evolving field.

Corticotropin-Releasing Factor

CRF is a 41-amino-acid neuropeptide (Vale *et al.* 1981) that mediates the response to stress by activating the hypothalamic-pituitary-adrenal (HPA) axis and by regulating neuronal activity in stress-responsive areas of the CNS. Following an acute stress experience (which may be real or perceived), CRF is released by parvocellular neurons of the paraventricular nucleus of the hypothalamus (PVN) into the median eminence and reaches the cells of the anterior pituitary through the microvasculature of the portal system. The binding of CRF to its receptor on the pituitary gland induces the synthesis and release of adrenocorticotropic hormone (ACTH) into peripheral blood circulation. ACTH reaches the adrenal gland and stimulates release of glucocorticoids that mediate several metabolic and neurophysiological effects of stress. Arginine vasopressin can be co-secreted with CRF during the stress response and contributes to the increase in ACTH levels (Itoi *et al.* 2004). Besides its role in the stress response, hypothalamic CRF is also responsible for circadian regulation of the HPA axis, with a peak in ACTH and glucocorticoid secretion at the onset of wakefulness and a trough 12 hours later. CRF is present in other brain regions within the CNS, notably within neurons of the locus coeruleus, the bed nucleus of the stria terminalis, and the dorsal raphe and amygdala, and it modulates the activity of these and other stress-responsive areas that express CRF receptors (Van Bockstaele and Valentino 2013; Young and Tong 2021).

CRF receptors are classified as CRF receptor type 1 and type 2 (CRFR1 and CRFR2) (Chen *et al.* 1993; Liaw *et al.* 1996). Both types of receptors are expressed in brain and peripheral tissue, with a higher prevalence of type 1 in the brain and of type 2 in the periphery. Other peptides that bind to these receptors with varying degree of affinity are urocortin-1 (Ucn-1), urocortin-2 (Ucn-2; also known as stresscopin-related peptide), and urocortin-3 (Ucn-3; also known as stresscopin) (Lewis *et al.* 2001; Reyes *et al.* 2001; Spina *et al.* 1996). CRFR1 and CRFR2 are both GPCRs that couple to G_s and activate cAMP-dependent PKA; however, evidence indicates that these receptors can also bind to G_q and $G_{i/o}$ in a tissue-specific manner. CRFR1s are highly expressed in the HPA axis and primarily mediate the activity of CRF neuropeptides under conditions of pronounced stress. Accordingly, CRF knockout mice and CRFR1 knockout mice show a severely reduced response of the HPA axis to stressful challenges (Smith *et al.* 1998). CRFR2 expression in the HPA axis is limited, but CRFR2 knockout mice still present an anxiogenic phenotype, with a rapid activation of the HPA axis and a lengthier recovery of the system after stress. This phenomenon might be explained by the fact that CRFR2s are highly expressed in neurons of the bed nucleus of the stria terminalis (BNST), which send inhibitory projections to the PVN, medial amygdala, and locus coeruleus and therefore normally inhibit HPA axis activity. Indeed, optogenetic activation of CRFR2 neurons in the BNST was found to reduce anxiety and to attenuate the neuroendocrine stress response (Henckens *et al.* 2017).

CRF is a well-known mediator of the pathophysiology of anxiety and depression. Numerous studies have reported a substantial link between depression and alterations in HPA axis activity (Keller *et al.* 2017); for example, increased levels of CRF in the cerebrospinal fluid, increased cerebrocortical CRF immunoreactivity, decreased CRFR1 binding, and decreased CRFR1 mRNA expression have been reported in postmortem

brain tissue of individuals who died from suicide (Sanders and Nemeroff 2016). Also, it has long been established that about 30%-50% of depressed patients demonstrate hypothalamic-pituitary-adrenocortical (HYPAC) hyperactivity, as revealed by resistance to the normal reduction in plasma 11-hydroxycorticosteroid produced by administration of the synthetic glucocorticoid dexamethasone (Carroll *et al.* 1968; Kocsis *et al.* 1985). Conversely, CRF hypoactivity has also been associated with certain subtypes of depression--namely, atypical and melancholic depression (Gold and Chrousos 2013; Kumsta *et al.* 2019). Given strong preclinical and clinical findings supporting the involvement of the CRF/CRFR system in anxiety and depression, a number of clinical trials using various CRFR1 antagonists were initiated; however, none produced satisfactory outcomes, either because of ineffectiveness or because of toxicity issues. Moving forward, it will be important to obtain a better understanding of the nuances of the CRF receptor family to allow development of molecules with a favorable safety profile that more reliably discriminate between CRFR1 and CRFR2. Additionally, therapeutic effectiveness may benefit from novel genetic and biochemical biomarkers capable of identifying individuals with a dysregulated CRF/CRFR system, for whom CRFR1 antagonists may be more effective as antidepressants or anxiolytics (Deussing and Chen 2018).

Oxytocin and Vasopressin

Oxytocin and arginine vasopressin (AVP) are two other neuropeptides gaining interest with respect to their relevance for psychiatric illnesses. These hormones have highly similar nine-amino-acid peptide sequences that differ by only two amino acids. Oxytocin signals through a GPCR (oxytocin receptor) that can bind to different G protein subtypes (G_q, G_i, G_o), depending on the concentration of the oxytocin ligand. AVP can bind to and modulate three types of vasopressin receptors: V_{1A}, V_{1B}, and V_2. V_{1A} and V_{1B} receptors are expressed in the CNS, especially in the olfactory bulb, anterior pituitary, cortex, hypothalamus, and hippocampus, and are coupled to $G_{q/11}$ proteins. V_2 receptors, largely present in the kidney, activate adenylate cyclase through G_s proteins.

Oxytocin and AVP are synthesized in magnocellular neurons of the PVN and the supraoptic nucleus of the hypothalamus. These neurons project their axons to the posterior pituitary gland (i.e., the neurohypophysis); from here, oxytocin and vasopressin vesicles are secreted directly into systemic circulation. As mentioned earlier, vasopressin can also be co-secreted with CRF. In the periphery, these hormones have important roles in the reproductive system during and after childbirth (oxytocin) and in the control of water reabsorption (AVP). In the brain, oxytocin and AVP act as neuromodulators of other neurotransmitter systems (e.g., the GABA and glutamate receptor systems [Bakos *et al.* 2018; Mitre *et al.* 2018]), and conversely, different neurotransmitters can regulate release of oxytocin and AVP and of other neuropeptides (Golyszny and Obuchowicz 2019).

The involvement of oxytocin and AVP in regulating emotions and social behaviors (parental, affiliative, and sexual behaviors for oxytocin; fear, aggression, and anxiety for AVP) is well established. For example, AVP has been shown to modulate aggressive behaviors and plasticity in the hippocampus through the V_{1B} receptors (Pagani *et al.* 2015). In a well-designed study, release of oxytocin within the amygdala was shown to be necessary and sufficient for modulation of fear memory and, with manipulation, to produce anxiolytic effects in mice (Hasan *et al.* 2019).

In addition to the role of oxytocin and AVP in modulation of emotional responses, a growing body of evidence points to the involvement of oxytocin and AVP signaling in cognitive functions, as well as in the etiology of neuropsychiatric disorders such as depression, bipolar disorder, autism spectrum disorder, schizophrenia, and borderline personality disorder (for a comprehensive review of this emerging field, see Abramova *et al.* 2020). Administration of oxytocin peptide intranasally has been adopted in clinical research and in therapeutic settings, following evidence that exogenous neuropeptides can cross the blood-brain barrier in small but functionally significant amounts via the receptor for advanced glycation end products (RAGE) (Yamamoto and Higashida 2020). Intranasal administration of oxytocin improved cognitive deficits and negative symptoms in individuals with schizophrenia (Ota *et al.* 2018), and it also improved social deficits and emotional dysregulation in individuals with autism spectrum disorder (Quintana *et al.* 2017). Study findings on the effects of intranasal oxytocin in depression have been mixed (MacDonald *et al.* 2013; Wong *et al.* 2021a). Improvements in social interaction in depressed patients were observed; however, in a subset of subjects with high introversion and a general tendency to self-isolate, oxytocin had anxiogenic effects, increased the bias to assign a negative valence to recalled events, and increased anhedonia). Thus, it appears that in depressed individuals, oxytocin may produce heterogeneous subjective effects that are sensitive to emotional context, individual personality traits, and attachment patterns (MacDonald *et al.* 2013; Wong *et al.* 2021a). Nevertheless, some evidence exists to suggest that intranasal oxytocin can be effective as an adjunct to SSRIs in improving symptoms in patients with treatment-resistant depression (Scantamburlo *et al.* 2015).

Although only a few reports have documented the use of modulators of the vasopressin system as therapeutics for mental disorders, some emerging studies indicate that this treatment is a viable option. As has been found for oxytocin, intranasal AVP has also been reported to have therapeutic potential in schizophrenia and in autism spectrum disorder (Geng *et al.* 2017; Parker *et al.* 2019). AVP can activate the HPA axis by stimulating AVP V_{1B} receptors located on the pituitary gland. Therefore, antagonists of V_{1B} receptors have been developed as potential antidepressants. In preclinical studies, direct antagonism of V_{1B} receptors successfully reduced stress-induced HPA axis activation and memory impairment (Barsegyan *et al.* 2015). Some of these antidepressant effects were reproduced in clinical trials, sparking hope for a potential use for V_{1B} receptor antagonists in depression therapy (Chaki 2021).

In conclusion, peptidergic neuromodulators are currently the focus of intense investigation for their potential use as standalone or adjunctive therapeutics for psychiatric disorders. Existing challenges to overcome include 1) the need to obtain a better understanding of peptide receptor pharmacology to help develop ligands and dosage regimens that differentiate between receptor systems in the CNS that regulate behavioral adaptation and those in the periphery that regulate homeostatic systems and 2) the need to develop more personalized approaches to therapy.

Opioids

Opioids, a class of drugs that act on opioid receptors, are commonly used for the treatment of moderate to severe acute, chronic, and inflammatory pain. The term *opiate* is often used interchangeably with *opioid*, and although all opiates are opioids, not all opioids are opiates. The term *opiate* refers to a drug that is derived from naturally occurring opium alkaloid compounds found in the opium poppy plant, whereas the term *opioid* encompasses any substance, whether natural, synthetic, or partially synthetic, that binds to opioid receptors.

The *naturally occurring opioids* are derived from the opium poppy plant (*Papaver somniferum*) and include opium, codeine, thebaine, and morphine. Historically (since ~ 3400 B.C.), opium was used to relieve pain, provide anesthesia, and induce sleep and was also used recreationally. Morphine, the primary active component of opium, continues to be the gold standard for treatment of pain to which all opioid analgesic drugs are compared. *Synthetic opioids* are compounds synthesized in a laboratory setting that have structures similar to those of naturally occurring opioids. Examples of synthetic opioids are fentanyl, methadone, carfentanil, and tramadol. Synthetic opioids have significant advantages over naturally derived opioids, including the capability for faster production (e.g., no time needed for plant cultivation) and lower costs. However, synthetic opioids and naturally occurring opioids have similar risks, including overdose and addiction. *Endogenous opioids*, discovered in the 1970s, are peptides that result from the proteolytic cleavage of precursor proteins, leading to the generation of more than 20 peptides. Cleavage of the precursor proteins prodynorphin, proenkephalin, proopiomelanocortin, and prepronociceptin produces dynorphins, enkephalins, endorphins, and nociceptin, respectively.

Both endogenous opioids and their opioid receptors are widely distributed throughout the central and peripheral nervous systems, particularly in regions that regulate pain, emotion, reward, stress responses, motivation, drug addiction, and autonomic control. The differential expression and location of endogenous opioids and their receptor subtypes likely account for the wide range of opioid-mediated effects.

Opioid receptors. ***Opioid receptor family and nomenclature*.** Opioid receptors are members of the large, seven-transmembrane-spanning GPCR family. There are three classical opioid receptors: mu (named after morphine), delta (named for the tissue--vas deferens--in which it was first identified), and kappa (named after the first ligand, ketocyclazocine, found to selectively activate the receptor). The approved opioid receptor nomenclature (as established by the Nomenclature Committee of the IUPHAR [NC-IUPHAR]) is summarized in Table 2-6. As defined by NC-IUPHAR, receptor classification is based on the endogenous ligands. For opioid receptors, the endogenous ligands are opioid peptides; thus, the receptors are designated as opioid peptide (OP) receptors. NC-IUPHAR has approved the use of Greek symbols for the three receptors--m, d, and k. These symbols can either stand alone or be abbreviated as mOP (or MOP, for mu), dOP (or DOP, for delta), and kOP (or KOP, for kappa). In addition to the three classical OP receptor subtypes, a fourth receptor subtype was identified that has close structural homology with and functional similarity to the OP receptors. This receptor--known as the opioid-receptor-like 1 (ORL_1) receptor, or the nociceptin opioid (NOP) receptor--is selectively activated by the endogenous ligand nociceptin/orphanin FQ (N/OFQ), which is derived from the precursor protein prepronociceptin. Although opioid ligands generally do not bind with high affinity to NOP receptors (an exception is buprenorphine [Toll *et al.* 2016]), the ORL_1 receptor is included as a nonopioid subcategory of the OP receptor family (Cox *et al.* 2015).

Opioid receptor heteromers. Substantial evidence supports the existence of functional and dynamic GPCR homomers and heteromers. All three classical opioid receptors have been shown to form heteromeric complexes with each other as well as with other classes of GPCRs. Although there is only one gene for each opioid receptor subtype, each receptor has been found to have more than one pharmacological subtype (e.g., dOP_1 and dOP_2 receptors; $kOP_{1\text{-}3}$ receptors). Receptor heteromers can have pharmacological properties--for example, ligand affinity, interprotomer allosterism, cellular signaling specificity, regulation--that are distinct from those of the individual receptors (Massotte 2015). It has been suggested that the propensity of

GPCRs to form opioid receptor heteromers (e.g., DOP-MOP, DOP-KOP) may explain the pharmacological subtypes of opioid receptors.

***Opioid receptor signaling*.** Opioid receptor activation leads to increased activity of a number of signal transduction pathways in cells of both the CNS and the periphery. The canonical signaling of opioid receptors is G_i protein mediated, leading to activation of three major inhibitory pathways known to reduce neuronal activity: 1) inhibition of adenylyl cyclase activity, 2) opening of GIRK ion channels, and 3) closing of voltage-gated calcium channels (Figure 2-20). In addition to coupling to G_i proteins, opioid receptors can signal via other G proteins as well as elicit non-G protein-mediated signaling to different intracellular signaling pathways. Furthermore, numerous mechanisms have been described whereby opioids can regulate receptor signaling, including phosphorylation, desensitization, and internalization. Phosphorylation of an opioid receptor can elicit b-arrestin recruitment to the receptor, which in turn elicits desensitization and internalization of the receptor. In addition, opioid receptor activation can lead to increased activity of the mitogen-activated protein kinases: ERK1/2, JNK, and p38. Opioid receptor activation has also been shown to elicit changes in the activity of transcription factors (e.g., cAMP response element-binding protein, DeltaFosB).

Biased signaling of opioids. Although effective as pain therapeutics for moderate to severe pain, opioid agonists are associated with serious adverse effects, including respiratory depression (which can lead to death), overdose, and substance use disorders. Efforts to develop opioid agonists that provide the same levels of analgesia without producing as many adverse effects have been based on the notion that a bias toward G_i protein activation and against b-arrestin recruitment would provide for more effective analgesia without producing adverse effects such as respiratory depression and constipation (Figure 2-21). Indeed, preclinical studies examining m opioid receptor agonists that are biased toward G_i proteins and away from arrestins have shown that these agents produce enhanced analgesia (Cunningham *et al.* 2019; Pineyro and Nagi 2021). However, other studies indicate that such biased agonists still produce respiratory depression and constipation (Gillis *et al.* 2020), suggesting that these m opioid receptor-mediated adverse effects are elicited--at least in part--by activation of other signaling molecules (i.e., other than b-arrestins and perhaps including G_i proteins).

Opioid receptor activation of G protein signaling leading to increased ion channel activity (GIRK and Ca_v channels) and inhibition of AC was thought to mediate analgesia, whereas b-arrestin signaling was associated with adverse side effects (e.g., constipation, respiratory depression). However, more recent studies suggest that b-arrestin signaling may not underlie the development of constipation and respiratory depression, whereas G protein-mediated pathways may contribute to the development of these adverse effects. Allosterism and opioid receptors. An allosteric ligand binds to a site on a receptor that is topographically distinct from the orthosteric ligand binding site; thus, both ligands can occupy the receptor at the same time. Consequently, an allosteric ligand can stabilize the receptor in a conformation for which the affinity and/or intrinsic efficacy of an orthosteric ligand can be different (enhanced or reduced). Importantly, the new receptor conformation stabilized by an allosteric ligand influences orthosteric ligand affinity and/or intrinsic efficacy in a ligand-dependent manner (Gentry *et al.* 2015; Kenakin 2021; Wenthur *et al.* 2014). This ligand dependence is also commonly referred to as *probe dependence*. Recently, in response to the opioid epidemic, the National Institute on Drug Abuse (NIDA) announced that identification of PAMs at the m opioid receptor is a medication priority (Rasmussen *et al.* 2019). Thus, current strategies in drug discovery are focused on identification of PAMs that can enhance the therapeutic effects of endogenous opioid peptides (preserving their temporal and spatial release patterns) and/or that can modulate the effects of opioids (e.g., fentanyl, morphine) such that analgesia is enhanced and adverse effects (e.g., respiratory depression) are minimized (Kandasamy *et al.* 2021; Pryce *et al.* 2021).

Opioid receptor expression in brain and physiological effects.

Clinically, opioids are used predominantly for treatment of pain. All opioid receptors can produce analgesic effects via activation of receptors expressed in brain regions involved in pain processing and perception as well as in the spinal cord and in the periphery. However, in addition to having specific brain region distributions, each receptor subtype can elicit physiological responses other than analgesia.

***Mu opioid receptors*.** Mu opioid receptors are expressed centrally at moderate to high densities in the cerebellum, nucleus accumbens, caudate nucleus, cerebral cortex, and amygdala. All opioids currently in clinical use for treatment of pain are m opioid receptor agonists. In addition, m opioid receptors are involved in reward processing of both natural stimuli and drugs of abuse, actions that promote recreational drug use and the onset of addictive behavior (for a review, see Lutz and Kieffer 2013). Importantly, the worldwide opioid epidemic is a result of abuse of opioids that target m opioid receptors. One of the approved treatments for opioid use disorder (which is considered a psychiatric illness [American Psychiatric Association 2013]) is methadone, a long-acting synthetic opioid agonist that has been used for nearly 50 years as a maintenance therapy to treat opioid use disorder. Furthermore, the long-acting ligand buprenorphine, which is a partial (weak) agonist at m receptors, an antagonist at k receptors, and a full agonist at NOP receptors, is also used to treat opioid use disorder (Cao *et al.* 2023; Watan Pal *et al.* 2021). The opioid antagonists naloxone (Narcan) and naltrexone (Vivitrol), respectively, are used to reverse severe respiratory depression following opioid overdose and to treat opioid and alcohol use disorders (Kranzler and Soyka 2018; Lee *et al.* 2018).

Delta opioid receptors. Delta opioid receptors are expressed in the cerebral cortex, amygdala, pontine nucleus, nucleus accumbens, and olfactory tubercle. d opioid receptor agonists have shown promise for treatment of chronic pain. However, in contrast to m receptor agonists, d opioid receptor agonists do not readily cause physical dependence, elicit respiratory depression, or produce rewarding effects. Although some older d opioid receptor agonists (e.g., SNC80) have been shown to induce mild epileptic seizures in rodents (Broom *et al.* 2002) and rhesus monkeys (Danielsson *et al.* 2006), second-generation d receptor agonists do not appear to produce these effects, perhaps due to biased signaling (Chung *et al.* 2015). Furthermore, studies suggest that d opioid receptor agonists can produce anxiolytic effects as well as promote positive affect (Valentino and Volkow 2018). Thus, there is increasing interest in the development of d opioid receptor agonists for the treatment of mood disorders such as depression and anxiety.

Kappa opioid receptors. Kappa opioid receptors are widely expressed in the CNS, including the mesolimbic system, hypothalamus, amygdala, and hypothalamic-pituitary-adrenal (HPA) axis. In contrast to m and d opioid receptor agonists, k opioid receptor agonists produce dysphoria and negative affects as well as psychotomimetic effects. Furthermore, dysregulation of the dynorphin/kappa opioid receptor (KOR) system has been shown to be involved in numerous psychiatric disorders, including depression and substance use disorders/addiction (Crowley and Kash 2015), as well as in both positive and negative symptoms of schizophrenia (Clark and Abi-Dargham 2019).

NOP receptors**.** NOP receptors are highly expressed in the ventral tegmental area, nucleus accumbens, and prefrontal cortex. Preclinical studies indicate that NOP receptor agonists are effective analgesics in primates, but not in rodents. However, NOP receptor agonists are neither rewarding nor aversive and can attenuate the rewarding effects of opioids as well as those of other drugs of abuse (Toll *et al.* 2016). In addition, activation of the NOP receptor via intracerebroventricular administration (or microinjection into the central amygdala) of its selective endogenous agonist nociceptin (N/OFQ) reduces anxiety-related behavior in rodents (Schroder *et al.* 2014). NOP receptor antagonists may have a role in treating depression (Redrobe *et al.* 2002). Although these agents are promising, much more work is needed to determine whether NOP receptors will be useful targets for therapeutics.

Conclusion

In this chapter we have provided an overview of neurotransmitters and their receptors in the brain that are relevant for psychiatric disorders and their treatment. We have emphasized signaling pathways for different neurotransmitters, novel signaling properties of drugs acting on receptors (e.g., biased agonism), the many types of specific receptors for neurotransmitters and their many different subunits, receptors existing as either homodimers or heterodimers, constitutive receptor activity, and the regional location of receptors and transporters. The reason for such detail is simple. The more the existence of such phenomena is recognized, the more targets become available for drug development that hopefully will offer advantages over existing drugs. In some cases, this knowledge has already borne fruit, but in other instances, preclinical data have not yet been translated into useful therapeutics in patients. Nevertheless, efforts are ongoing, and there is no doubt in the authors' minds that the next 10 years will lead to much-improved therapeutics based on such detailed knowledge of brain function.

CHAPTER 3

Genetics and Epigenetics

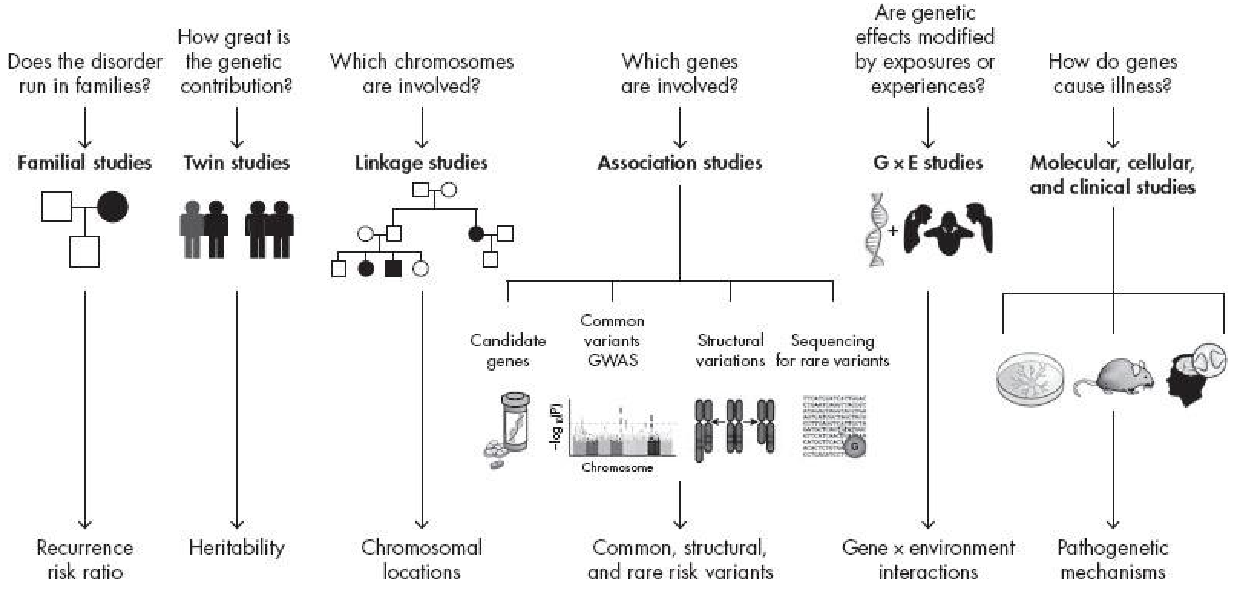
Elisabeth B. Binder, M.D., Ph.D.

Genetics and genomics are among the most important tools in modern psychiatric research. Genomics in psychiatry has developed into a multidisciplinary assembly of huge data. In this chapter, we cover basic concepts as well as the latest methodologies and define key terms currently used in psychiatric genomics. An overview of the genetic methods available in psychiatric research today is illustrated in Figure 3-1. Our goal is to facilitate physicians' and scientists' interpretation of the avalanche of genetic and genomic data, including epigenetics, that are accumulating in psychiatry. The potential impact of this new information on improving diagnosis and treatment of these disorders is discussed. Throughout this chapter, terms in common use in the genetics and genomics literature are italicized on first use and are defined.



Does the disorder run in families?
How great is the genetic contribution?
Which chromosomes are involved?
Which genes are involved?
Are genetic effects modified by exposures or experiences?

Epidemiological Basis for Genetic Contributions to Neurobehavioral Disorders

Insights From Adoption and Twin Studies

Genetic epidemiological studies have established that most psychiatric disorders have a substantial genetic component. Genetic epidemiology uses family, adoption, and twin studies to assess the contribution of familial, environmental, and genetic factors to a trait of interest. A family study uses a *pedigree* (a type of family tree) to establish whether a given disorder "runs in the family"; however, these studies cannot easily distinguish whether such familiality is due to genetic or environmental factors. An everyday example of this distinction is the difference between the ability to acquire language (a genetic trait that distinguishes humans from other species) and the native language spoken by a given person (familial but entirely environmentally determined). Large registries of familial data, such as the Swedish National Register, have provided strong evidence for heritability of psychiatric disorders. Analysis of 3 million full and half-siblings showed that for most disorders, over 50% to up to 80% of the variance can be attributed to genetic factors, with strong evidence for a large proportion of shared genetic factors (Pettersson *et al.* 2016).

Adoption and twin studies differentiate between genetic and environmental influences on traits by accounting for each separately. Adoption studies investigate whether an individual's risk for a psychiatric disease depends on the mental health status of the biological or adoptive parents to disentangle genetic (i.e., similarity to biological parents, who had little or no interaction with the adoptee) from environmental (i.e., similarity to adoptive parents, who provided the environment) influence (Cadoret 1986; Tienari and Wynne 1994; Tienari *et al.* 2004). Practical, ethical, and legal obstacles make large-scale adoption studies difficult to conduct. Twin studies, while also challenging, are more tractable, and large twin registries are now available globally (Busjahn 2002).

In twin studies, the degree of correlation between twins for an investigated trait is compared for monozygotic (MZ; i.e., identical) and dizygotic (DZ; i.e., non-identical) twins to gain information on the amount of genetic and environmental influence on a certain trait (Figure 3-2). Although neither the pre-nor the postnatal environments of twins are exactly identical, for a first approximation, MZ and DZ twins are equally correlated for relevant environmental exposures (Kendler and Gardner 1998). The trait correlation between MZ and DZ twins therefore allows estimation of the degree to which the additive genetic, shared, or individual-specific environment contributes to the likelihood of a given trait.

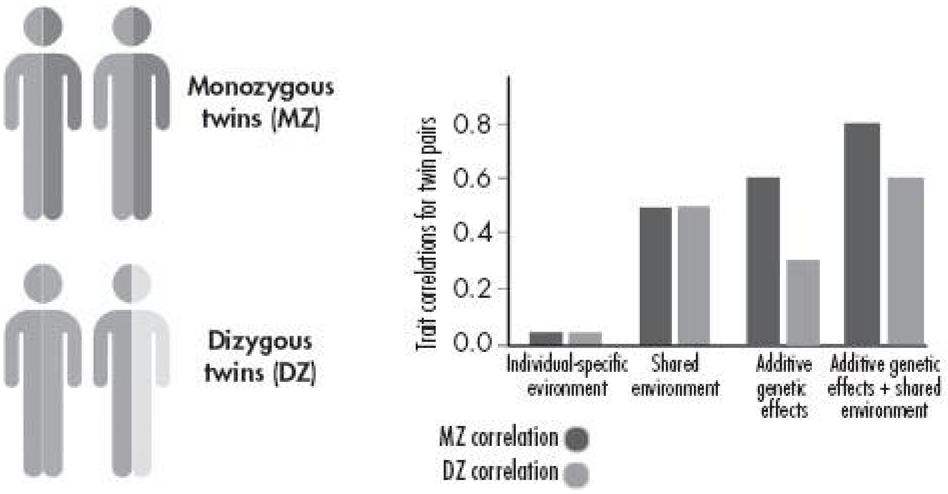

FIGURE 3-2. Patterns of intrapair correlations in twins and the source of variance implied.

See Plate 21 to view this figure in color.

Correlation of phenotypes/traits between monozygotic (MZ) and dizygotic (DZ) twin pairs illustrating different scenarios of genetic and environmental contributions to disease. Intrapair correlations of around zero imply effects of individual-specific environment. Equal intrapair correlations that are greater than zero for MZ and DZ twins imply effects of shared environment. Correlations for MZ twins that are twice as great as those for DZ twins imply additive genetic effects. Correlations for MZ twins that are greater than--but not twice as great as--those for DZ twins imply additive genetic effects and shared environment effects. Correlations of less than 1.0 are likely mediated by individual-specific environment effects.

In the largest conducted meta-analysis of twin studies (over 14.5 million twin pairs), an average 49% heritability was found for the 18,000 human traits examined. For most of the traits (two thirds), the correlation between MZ twins was double that seen for DZ twins, indicating a simple genetic model with independent effects of genes. Nevertheless, for the remaining third, the effects of genes cannot be independent (Polderman *et al.* 2015). The data are available through the MaTCH (Meta-Analysis of Twin Correlations and Heritability) resource (http://match.ctglab.nl/#/home). Twin studies have firmly established genetic contributions for all psychiatric disorders, with *heritability estimates* (the proportion of risk for a disorder attributable to the additive effects of genes) ranging from 30% to 80% for most common psychiatric disorders (Table 3-1). A discrepancy exists between heritability estimates from family studies and those from population cohorts, which are always lower. For example, heritability estimates for schizophrenia from twin studies averaged about 0.8 (Sullivan *et al.* 2003), whereas a Swedish population study estimated a heritability of 0.65 for schizophrenia and 0.59 for bipolar disorder (Lichtenstein *et al.* 2009). Using a population cohort of more than 2.6 million Danes, Wray and Gottesman (2012) estimated a heritability of 0.67 for schizophrenia, 0.32 for major depressive disorder (MDD), and 0.62 for bipolar disorder.

Additionally, genetic epidemiology allows exploration of more complex questions, such as whether the same genetic risk factors are shared by different psychiatric disorders (cross-disorder risk) and between sexes and whether these genetic risk factors can moderate or be moderated by the effects of environmental risk factors (Kendler 2001). As

such, they can therefore shape follow-up molecular genetic studies. For example, a twin study suggested that genetic risk factors for MDD could in part act by increasing vulnerability to stressful life events (Kendler 1995). Genetic epidemiological studies have been an important foundation of psychiatric genetics and are likely to continue to contribute more elaborate disease models for future molecular genetic analysis. The major limitation of these studies, however, is that the estimated heritability of twin studies is only an estimate of the aggregate genetic effect. Heritability does not provide any information about which specific genes contribute to the risk for a disorder.

Using a novel method of approximating the genetic risk using extended pedigrees, Kendler *et al.* (2020, 2021) recently calculated family genetic risk scores (FGRS) for a number of psychiatric disorders using the Swedish national sample. The authors reported that all diagnostic groups had elevated FGRSs and found clear patterns across disorder groups and higher FGRS in individuals with earlier age at onset and higher recurrence. This work highlights the need to look beyond specific diagnoses of individuals, toward their genetic risk pattern for all disorders.

Human Genetic Variation

Genetic epidemiological studies can indicate the presence of an aggregate genetic effect but cannot identify which type of or how many variations contribute to the effect.

In this section, the glossary provides an overview of the types of genetic variation, followed by some examples illustrating the implications of each variation type in psychiatric disorders.

Glossary of Molecular Genomic Variation Terms

An *allele* is a variation in the DNA sequence that occurs at a particular polymorphic site on one chromosome. Every individual with a normal set of chromosomes has two alleles for each polymorphism on the *autosomes* (non-sex chromosomes, numbers 1-22). On the sex chromosomes, men have only one allele each for all polymorphisms located on the X and Y chromosomes, whereas women carry two copies of each X-linked allele.

A *genotype* is the combined description for the variation at a particular corresponding point on homologous chromosomes and is expressed as two alleles. When the alleles on both chromosomes are the same, it is a homozygous genotype. When the alleles differ, it is a heterozygous genotype.

A *haplotype*, a term derived from the abbreviation of *haploid genotype*, is the sequence of alleles along an adjacent series of polymorphic sites on a single chromosome that are inherited together due to strong linkage disequilibrium (see subsection "Linkage Dysequilibrium" later in this section).

Copy number variation (CNV) describes chromosomal regions in which one or more genes are deleted or occur in multiple copies.

Insertion/deletion polymorphisms are microscopic insertions and deletions of one to hundreds of base pairs and are much smaller than CNVs.

Microsatellites are a type of polymorphisms, also called *short tandem repeats* (STRs) or *variable number of tandem repeats* (VNTRs). About 30,000 of these polymorphisms exist in the human genome, and they serve as markers for genome-wide linkage analysis (see "Linkage Studies" subsection later in this chapter for more detail).

Single nucleotide polymorphisms (SNPs) consist of a single base difference at a particular site in the genome, commonly a cytosine-to-thymine (C-to-T) exchange. Most SNPs have two alleles, but SNPs with three or four different alleles have been reported.

Molecular Genomic Variation in Psychiatric Disorders

Psychiatric disorders are complex genetic disorders. Genetic epidemiological studies have established that psychiatric disorders are not single-gene disorders inherited in a *Mendelian fashion* (i.e., in a clear recessive, dominant, or X-linked fashion), although there are rare families in which psychiatric phenotypes are inherited in this way (Brunner *et al.* 1993). A genetic disorder can be complex for several reasons, as outlined in Table 3-2. In the following sections, we describe different types of genetic variants and specific examples linking them to psychiatric disorders and traits. Table 3-3 focuses on larger variants observable at the chromosomal level, including translocations and larger deletions.

TABLE 3-2. Complexity of genetic disorders

---

* *Incomplete penetrance*. Not every person carrying the disease allele(s) has symptoms.

* *Phenocopy occurrence*. Nonheritable traits caused by environmental factors can resemble traits caused by a genetic mutation.

* *Locus heterogeneity*. Variants in different genes can lead to similar or identical disease phenotypes.

* *Allelic heterogeneity*. Different patterns of variation within the same gene or genes can lead to similar or identical disease phenotypes.

* *Polygenic inheritance*. Additive or interactive effects of variation at multiple genes (i.e., epistatic effects) are necessary for an illness to manifest.

* *Gene-by-environment interaction*. A disorder manifests in response to environmental factors only in the context of predisposing genetic variants. An extreme example of such interaction is phenylketonuria, in which exposure to dietary phenylalanine causes severe neurobehavioral impairment in individuals carrying two mutant copies of the locus encoding phenylalanine hydroxylase; limitation of dietary phenylalanine prevents the neurobehavioral disorder.

* *High frequency of the disorder and the predisposing alleles*. It appears increasingly likely that common disorders represent final common outcomes of a variety of combinations of environmental and genetic predisposing factors. Thus, two individuals, even within the same family, might manifest clinically indistinguishable disorders for different underlying reasons.

* *Other genetic mechanisms of inheritance*. Alternative genetic mechanisms--for example, mitochondrial inheritance or alteration of the genome across generations, such as occurs in trinucleotide-repeat-expansion disorders (e.g., Huntington's disease and fragile X syndrome) or in epigenetic disorders--may be involved in producing a disorder. Epigenetic disorders result from alterations in the genetic material that do not involve changes in the base-pair sequence of DNA. Examples of epigenetic disease include the imprinted disorders Angelman syndrome and Prader-Willi syndrome, in which parent-of-origin-dependent

chemical modification of DNA produces different phenotypic outcomes from the same chromosomal deletion.

TABLE 3-3. Larger genetic variants observable at the chromosomal level

Variation in chromosomal number

The human genome has approximately 3 billion bases that are distributed over 23 chromosome pairs, with 22 pairs of autosomes and 1 pair of sex chromosomes, X and Y. The most obvious genetic variations can be observed at the light microscope level in the karyotype. This approach visualizes metaphase chromosomes using histological procedures, allowing identification of each specific pair of chromosomes and variations in the total number of chromosomes, such as unisomies and trisomies.

Translocations

Karyotypic examination and other cytogenetic techniques such as fluorescent in situ hybridization (FISH) can detect large-scale chromosomal abnormalities, such as translocations, deletions, or duplications of large regions of chromosomes. In a large Scottish pedigree, a balanced translocation between chromosomes 1 and 11 appears to be causally linked to a series of major psychiatric disorders, including schizophrenia, bipolar disorder, recurrent major depressive disorder, and conduct disorder (St Clair *et al.* 1990). This *balanced translocation* (which exchanged parts of chromosome 1 with parts of chromosome 11 to produce two abnormal chromosomes but no net loss of chromosomal material) disrupts two genes at the translocation breakpoint on chromosome 1, termed *disrupted in schizophrenia* (*DISC*) *1* and *2* (Millar *et al.* 2000, 2001). Subsequent molecular analysis has provided strong evidence that variation in *DISC1* can alter the risk for schizophrenia (Porteous *et al.* 2006).

Deletions

Microdeletions occurring on the long arm of chromosome 22 have received considerable attention as cytogenetic risk factors for the development of schizophrenia (Karayiorgou and Gogos 2004). In the 22q11 deletion syndrome, 1.5-3.0 million base pairs (bp) of DNA are missing on one copy of 22q. There is a reported 10-20 times higher prevalence of the 22q11 deletion in patients with schizophrenia (Rees *et al.* 2014b), and duplications of 22q11.2 might prove protective (Rees *et al.* 2014a).

Duplications

Duplications of the long arm of chromosome 15 (15q11-13) are the most frequent cytogenetic anomalies in autism spectrum disorder (ASD), occurring in approximately 1%-2% of cases (Cook 2001). This duplication syndrome cannot be clinically differentiated from idiopathic autism (Veenstra-VanderWeele and Cook 2004), indicating that a complete workup of ASD should include testing for this cytogenetic abnormality as well as several others (Martin and Ledbetter 2007). Interestingly, deletion of this same region of 15q is associated with Angelman syndrome when the deletion occurs on the maternal copy of chromosome 15 and with Prader-Willi syndrome when the deletion occurs on the paternal chromosome.

Copy Number Variations

Rare CNVs in specific chromosomal locations have been associated with a strongly increased risk for neurodevelopmental disorders, including autism spectrum disorder (ASD) and developmental delay, as well as schizophrenias. These rare CNVs include deletions at 1q21.1, *NRXN1*, 3q29, 15q11.2, 15q13.3, and 22q11.2, and duplications at 1q21.1, 7q11.23, 15q11.2-q13.1, 16p13.1, and proximal 16p11.2. They are very rare in the general populations but are observed cumulatively in a percentage of the above-named disorders with a strong penetrance and odd ratios to develop the disorder of up to 50-fold or more. In most cases, these CNVs include more than one gene (Kirov 2015; Rees and Kirov 2021).

CNVs of the cytochrome P450 (CYP) genes, including *CYP2D6*, which are important for the metabolism of many antidepressants, antipsychotics, and mood stabilizers (Kirchheiner *et al.* 2004), provide a prominent example of the importance of CNVs to pharmacogenetics (Santos *et al.* 2018). The reported range of copy numbers of *CYP2D6* is from 0 to 13. The number of functional copies of *CYP2D6* directly negatively correlates with plasma levels of metabolized drugs, such as the tricyclic antidepressant nortriptyline (Bertilsson *et al.* 2002). It is important to bear in mind the population-specific frequencies (Santos *et al.* 2018) and to continue investigating specific subgroup populations (Ramirez *et al.* 2019).

Insertion/Deletion Polymorphisms

Among the most famous insertion/deletion polymorphism in psychiatric genetics is a common functional polymorphism in the promoter region of the serotonin transporter gene, *SLC6A4*, referred to as the serotonin transporter-linked promoter region (5HTTLPR) (Gelernter *et al.* 1999; Heils *et al.* 1996; Lesch *et al.* 1996; Nakamura *et al.* 2000). The 5HTTLPR has been associated with altered basal activity of the transporter, most likely related to differential transcriptional activity (Heils *et al.* 1996; Lesch *et al.* 1996) or differences in serotonin transporter binding potential (Parsey *et al.* 2006). It has been associated with increased risk for many psychiatric disorders, mainly mood and anxiety disorders; treatment response to antidepressant drugs, mainly selective serotonin reuptake inhibitors; and the moderation of adversity and stress-related psychiatric risk, although larger meta-analyses do not always support findings from the initial smaller studies (e.g., Crawford *et al.* 2013; Culverhouse *et al.* 2018).

Variable Number of Tandem Repeats

VNTRs not only serve as genetic markers for linkage analysis but also may produce functional variation within genes by altering gene regulatory elements and thus gene expression levels. Such VNTRs have been identified in a number of genes--including genes of the dopaminergic system, such as the dopamine transporter (DAT) gene *SLC6A3*, the *DRD4* locus encoding the dopamine D_4 receptor, and the dopamine b-hydroxylase gene (*DBH*), as well as the monoamine oxidase A gene (*MAOA*)--and associations with many psychiatric, behavioral, and brain phenotypes have been reported (Gatt *et al.* 2015). However, medium to strong functional effects on gene regulation have been confirmed only for *DBH* and *MAOA*. Both polymorphisms have been associated with a multitude of behavioral and psychiatric phenotypes (Tunbridge *et al.* 2019).

Single Nucleotide Polymorphisms

The discovery of SNPs has revolutionized psychiatric genetics among other fields (Altshuler *et al.* 2000; Sachidanandam *et al.* 2001). By 2020, more than 2 billion human SNPs had been catalogued in public databases (e.g., dbSNP; www.ncbi.nlm.nih.gov/projects/SNP). SNPs are the most common type of genetic variation and may represent up to 90% of all genetic variations. Besides being very frequent in the genome (SNPs occur, on average, every 300 bases), they are also amenable to high-throughput genotyping methods (Kim and Misra 2007; Kwok 2000). Since SNPs are common (essentially each gene of interest has several known SNPs) and cheap to genotype, they represent the markers of choice for complex trait genetic association studies that now cover the whole genome in so-called genome-wide association studies (GWAS).

Besides serving as genetic markers for chromosomal loci in association studies, SNPs also can have functional relevance themselves. SNPs in regulatory regions can alter the transcriptional regulation of a gene, SNPs in regions relevant for messenger RNA (mRNA) splicing can alter splice sites, and SNPs in protein-coding exons can encode differences in the primary amino acid sequence. Interestingly, when one considers the occurrence of SNPs across the genome, one observes that SNPs are most dense in intergenic and intronic regions but scarcer in putative regulatory regions and exons, suggesting selection against putatively functional genetic variants (Altshuler *et al.* 2000; Sachidanandam *et al.* 2001). Within exons, SNPs that do not cause an amino acid exchange due to the degenerate code are called synonymous SNPs, as opposed to nonsynonymous SNPs, which lead to amino acid substitution. One nonsynonymous SNP that has been associated with psychiatric phenotypes is the catechol-O-methyltransferase gene (*COMT*) polymorphism Val^{158}Met affecting the temperature lability of this enzyme's activity (Lachman *et al.* 1996; Lotta *et al.* 1995). The Val/Val genotype more rapidly inactivates, following an additive genetic model. This SNP seems to affect dopamine transmission--particularly in the frontal cortex, where expression of the dopamine transporter protein is relatively low--and has been associated with differences in executive cognition and functional activity of the prefrontal cortex during working-memory tasks (Egan *et al.* 2001; Goldberg *et al.* 2003; Joober *et al.* 2002; Mattay *et al.* 2003). Although it was hypothesized that this polymorphism also could alter the risk for schizophrenia (particularly because *COMT* resides in the 22q11 region, the deletion of which has been associated with schizophrenia), larger association studies and meta-analyses do not fully support that conclusion (Fan *et al.* 2005; Farrell *et al.* 2015; Okochi *et al.* 2009).

Identification of Risk Loci for Psychiatric Disorders

From the cumulative evidence of psychiatric genetic studies, including the molecular studies discussed in detail below, one can conclude that psychiatric disorders fit a

polygenic model of inheritance, with many polymorphic loci of low effect size contributing to disease risk in a mainly additive fashion (Wray *et al.* 2018).

In the following subsections, we describe methods for identifying these genetic loci associated with psychiatric disease risk. We first explain cytogenetic studies and linkage studies and then focus on what is now the most commonly used identification method: association studies.

Cytogenetic Studies

Disruption of chromosomal integrity by rare events such as balanced translocations has facilitated gene discovery in a variety of diseases and holds significant promise for similar applications in psychiatric illness (Pickard *et al.* 2005). Advances in techniques such as chromosome painting, high-resolution fluorescent in situ hybridization (FISH), and, most recently, genome-wide analysis of copy number variations using microarrays have made it possible to identify disruptions in chromosomal architecture to single-base resolution, thus facilitating identification of specific genes in families cosegregating mental illness and cytogenetic abnormalities. Such data then may be used to generate testable hypotheses about the role of a particular gene in disease pathophysiology. The *disrupted in schizophrenia* (*DISC*) *1* and *2* genes provide clear examples of specific genes implicated in mental illness following their discovery through careful molecular analysis of a cytogenetic anomaly.

Linkage Studies

In the 1980s and 1990s, many genes for Mendelian disorders were successfully identified with linkage analysis in large families. Linkage relies on the principle that, on average, chromosomes from parents differ from those of offspring by only one meiotic crossover event. During *meiosis*--the cell divisions that produce gametes by reducing the diploid genome (i.e., two chromosomes of each pair per cell) to a haploid genome (one copy of each chromosome per spermatocyte or ooctye)--homologous grandparental chromosomes (i.e., paternal and maternal to the parents of the offspring of interest) make physical contact and exchange homologous regions (referred to as *crossing over*) to give rise to a new set of chromosomes in which each gametic chromosome is a mix of grandparental sequences. This crossing-over process produces recombinations that can then be tracked with molecular markers to delineate the ancestral origin of each chromosomal region in the offspring.

Classically, linkage studies use from several hundred to a few thousand microsatellite markers, evenly spaced across the genome. These markers are then genotyped in large families in which the disease of interest is common. To identify positions in the genome that may be involved in the disease, one tracks whether marker alleles are inherited by affected relatives more often than would be expected by chance (i.e., linkage tests whether a particular chromosomal region cosegregates with the disease). A quantitative measure of the likelihood of a particular pattern of marker-disease cosegregation is the *logarithm of odds* (LOD) score, with a LOD score of 3.3 or greater being required before significant linkage is accepted (Lander and Schork 1994). Classical linkage approaches have been very successful in identifying monogenic diseases that follow clear, simple patterns of inheritance, but they have been far less successful in complex psychiatric disease.

Association Studies

While linkage studies allow the investigation of whether a variant segregates with a disease or phenotype in a pedigree, association studies can investigate whether a variant is more or less common in cases versus controls or if it associates with a quantitative trait. Given the complex, polygenic inheritance of psychiatric disorders, this method in now the most commonly used in psychiatric genetics. To help interpret association studies, we first need to introduce two key concepts, which are important for their design and understanding: linkage disequilibrium and population stratification.

Linkage Disequilibrium

GWAS rely on the principle that even unrelated individuals share very small stretches of chromosomal DNA derived from a distant common ancestor. In the case of a disease-predisposing mutation, some proportion of ill individuals will share that mutation arising from an original common ancestor. As the variant is passed down from generation to generation, meiotic recombination events will shrink the size of the initial piece of ancestral chromosome that is inherited together with the disease mutation. On these small ancestral stretches of chromosome (perhaps several thousand to several hundred thousand base pairs in length), nonfunctional "marker" polymorphisms close to the disease mutation will "ride" through generations together with the disease variant. Such markers (e.g., SNPs) thus can serve as surrogate "tags" for the disease mutation. Note, however, that as generations pass and individuals become ever more distant relatives (to a point when the social/cultural "memory" of the genetic relationship is usually lost), different families will produce recombination events at different points near the disease mutation. Therefore, at a population level, unrelated individuals carrying the disease marker will carry variable lengths of DNA upon which markers linked to the disease variant ride. Stated another way, unrelated individuals carrying the disease variant will carry haplotypes that become more similar to one another as the boundaries of the haplotypes are moved closer to the disease variant. Thus, the closer a marker is to the disease variant, the more likely it is to be originally linked to the variant. When a marker is close enough to a disease marker that the number of recombination events in the population has not yet completely randomized, and the odds are high that it is on the same ancestral stretch of DNA (haplotype) as the disease variant, the marker and the disease variant are correlated and are said to be in *linkage disequilibrium* (LD). Knowing the allele of a marker variant in LD with a disease variant can therefore allow one to predict the allele of the disease variant (i.e., the marker and the disease variant are not statistically independent).

Several factors influence the length of DNA over which LD occurs. The most important are the geographic origins of the population from which an individual is drawn and the history of that population. For example, sub-Saharan African populations are ancient and reflect the greatest proportions of the total human pool of variation, because most of the history of the human species predates migration of humans out of Africa. Therefore, on average, sub-Saharan African populations have undergone the greatest number of recombination events since a given pair of unrelated individuals shared a common ancestor. Those individuals thus share only short stretches of ancestral chromosomes (which are said to be *identical by descent*, or IBD). Non-African populations all derive from a relatively small number of migrants who left Africa within approximately the last 100,000 years. Thus, Europeans, Eastern Asians, or Native Americans share longer stretches of DNA IBD within their respective continental groups than do sub-Saharan Africans (Daly *et al.* 2001; Gabriel *et al.* 2002; Patil *et al.* 2001; Reich *et al.* 2001). At the other extreme, individuals from reproductively isolated populations, in which a small founder population has expanded with little admixture (i.e., introduction of outside individuals into the mating pool), share longer blocks of ancestral chromosomes that are IBD (Shifman and Darvasi 2001). An example is the Icelandic population, which derives almost exclusively from a small number of migrants who arrived on the island only several hundred years ago (Helgason *et al.* 2003).

Another factor contributing to the complexity of patterns of LD is the fact that recombination events do not occur with the same likelihood across all parts of the genome (Phillips *et al.* 2003; Reich *et al.* 2002). In addition to a general pattern, in which more telomeric regions of chromosomes are more likely to recombine than centromeric regions, specific "hot spots" of recombination have been identified that are spaced unevenly along chromosomes. This variation across the genome in the likelihood of recombination results in the observation that certain stretches in the genome (sometimes referred to as blocks) have undergone relatively little recombination over the generations and therefore show strong LD among SNPs in the region. Such regions of high LD can span millions of bases, whereas other regions in the same population have recombined more frequently, resulting in very short blocks of LD (e.g., < 5,000 base pairs). Within a block of LD, alleles of adjacent variation thus do not co-occur in random patterns but can be predicted and form a limited number of haplotypes (much less than the statistically possible combination of all alleles of all variations in the LD block). For this reason, such regions of high LD are also called *haplotype blocks* (Daly *et al.* 2001; Gabriel *et al.* 2002; Patil *et al.* 2001; Reich *et al.* 2001).

To date, there remains a huge diversity issue in genetic studies, with a massive overrepresentation of GWAS carried out in European populations (Popejoy and Fullerton 2016). The ethnicity of the study population must always be taken into consideration; although Mendelian (monogenic) disorders may cross populations, oligogenic or polygenic disorders will have limited transfer (Curtis 2018). A variant may be tagged by different SNPs in different ethnicities (allelic heterogeneity). When risk is assessed by tagging SNPs, LD strength will affect associations across populations.

From the Human Genome Project came HapMap (genotyping) and subsequently the 1000 Genomes Project (next-generation sequencing), which catalogue human genetic variations. These projects describe LD structures, providing a high-resolution map of the landscape of human genetic variation. Today, the richest database is the Genome Aggregation Database (gnomAD; http://gnomad.broadinstitute.org), which holds 15,798 whole genomes and 125,748 exomes. The newly released version 3.0 (2021) contains more than 76,000 genomes from various populations (Karczewski *et al.* 2020). These catalogs are all publicly available genomic datasets and have provided validation for many SNPs in databases such as the dbSNP.

Population Stratification

Frequencies of specific alleles can vary to a large degree among different populations. Spurious associations can thus be found if subjects for a genetic association study are

sampled from multiple subpopulations with different genetic ancestries (and thus with different allele frequencies in specific loci) in different proportions in case and control participants. Differences in allele frequencies between comparison groups can thus result from differences in the population structure of the sample alone, without any causal relationship to the outcome of interest. This problem is called *population stratification* and is exemplified by the hypothetical example of the "chopsticks gene" (Hamer and Sirota 2000).

Several methods have been developed to address population stratification in genetic association studies. Family-based approaches to genetic association studies, such as the transmission disequilibrium test

(TDT; Spielman *et al.* 1993) and the haplotype-relative risk (HRR) method (Knapp *et al.* 1993), are robust to population stratification. Population stratification cannot arise because each family provides its own control, and because the proband is always matched for the population background of the parents, population stratification cannot arise. However, such family designs are often not practical for large-scale studies or studies with late disease onset.

To control for population stratification in case-control studies, several methods have been suggested. The most commonly used method nowadays involves the use of genome-wide genotype data combined with principal component analysis to identify population substructures (Price *et al.* 2006). First, a matrix across all sample pairs reflecting the number of identical genotypes per pair is constructed. Second, the main axes of genome-wide genetic variation, also called *principal components*, of this matrix are calculated and plotted against each other to identify possible population outliers or clusters. These main (principal) components are then included as covariates in subsequent association analyses to correct for population admixture. Principal component maps are used to show how genetic similarity declines with geographical distance (see Novembre and Stephens 2008 for more details).

Genome-Wide Association Studies

The knowledge of the human genome and of its linkage disequilibrium structure, as well as technological advances, has made it possible to test genome-wide genetic association for psychiatric traits and disorders on a large scale. Both methods using array technology for genotyping and next-generation sequencing methods are used and can be applied in very large cohorts, with costs of genome-wide SNP genotyping arrays well below 50 US$ and genome-wide sequencing approaches below 600 US$ per sample.

How Many SNPs Are Needed?

The presence of linkage disequilibrium in the human genome allows investigators to evaluate a large extent of the common genetic variation through a much-reduced number of selected markers. Thanks to the catalogues of human genetic variation outlined earlier in this chapter, the genetic variability of the entire genome can be covered to a reasonable extent using SNP arrays. SNP arrays are high-throughput DNA microarrays that measure selected SNPs and small CNVs that tag LD blocks across the genome. Using the data from several hundred thousand SNPs is thus sufficient to cover most common variants in Europeans; more variants are necessary in African populations with shorter LD blocks (for a review, see Hirschhorn and Daly 2005). The genotypes of these tag variants can then be used to infer the genotypes at all known

sites with similar allele frequencies using imputation algorithms. *Genotype imputation* refers to a method that estimates genotype probabilities of SNPs that are missing in the study population, because of quality control or because they have not been covered by the used genotyping arrays. This estimation is based on reference samples such as the HapMap or the 1000 Genomes Project. These reference samples have been sequenced genome-wide, and hence a high number SNP genotypes is available. There are a variety of imputation tools that can be used (for more details, see Shi *et al.* 2018). In all of these methods, probabilities of SNP genotypes in the study population are estimated based on the LD structure between SNPs in the reference sample. Usually, estimated genotypes of those SNPs that could be predicted with a high probability are then used for further association analysis. Naturally, this estimation works well in regions of the genome in which a lot of SNPs in high LD are present. Furthermore, the reference sample and study sample should be from the same ethnic background; otherwise, LD patterns in the reference sample might not reflect the LD structure of the study sample.

A major drawback of whole-genome LD-based array approaches to association testing is that most sequence variation in the genome is rare, and rare variants are not tagged to the same extent as the more common variants (allele frequencies over 1% in a given population) on current arrays. Thus, to the degree that the genetic underpinnings of complex disease deviate from the "common disease, common variant" hypothesis, whole-genome SNP scans will be inadequate to detect all associated genes (Zwick *et al.* 2000). This concern is not merely theoretical, because rare variants also clearly contribute to complex disease--most notably ASD (Satterstrom *et al.* 2020). In all likelihood, complex disorders represent a mixture of contributions from rare and common variants, so that methods appropriate for both types of variation will need to be implemented.

Whole-genome sequencing, or the more focused approach of whole-exome (only the RNA/protein coding part of the genome) sequencing, has yielded important insights into the contribution of rare variants to most psychiatric disorders (Satterstrom *et al.* 2020; Takata 2019; Xu *et al.* 2011).

How Many Individuals Are Needed?

Genome-wide associations require a massive correction for multiple testing, so *P* values less than 5×10^{-8} have to be achieved for an association to be considered genome-wide significant. These necessarily low alpha levels, together with the expected low ORs associated with identified common susceptibility variants or the extremely low allele frequency of rare variants, require large sample sizes for adequate power. When one surveys genome-wide association discoveries over time, it can be seen that the larger the sample size, the more genome-wide association hits are found (see Figure 2 ["Increase in Number of Loci Identified as a Function of Experimental Sample Size"] in Visscher *et al.* 2012; www.ncbi.nlm.nih.gov/pmc/articles/PMC3257326/figure/fig2). Since 2009, the number of genomic loci found to be associated with schizophrenia, for example, has risen dramatically as a result of ever more cases being available, and discovered loci increased from zero in 2009 to 248 in 2020 (Table 3-4).

Power (i.e., the probability of obtaining a true-positive result) is determined by sample size, allele frequency, effect size, and significance level. For example, considering a quantitative trait and setting the alpha level to 5 x 10^{-8}, more than 10,000 individuals would be needed to detect a variant that explains 0.2% of the variance with a power of at least 80% (Visscher 2008). Current GWAS now often include more than 100,000 individuals. These sample sizes can be reached only within consortia that combine samples from many different studies and meta-analyze them together, such as the Psychiatric Genomics Consortium, a large-scale international collaboration (www.med.unc.edu/pgc) that continues to advance genetic discovery in psychiatry (Sullivan 2010). The Psychiatric Genomics Consortium has many working groups for the various psychiatric disorders and psychiatric traits as well as cross-disorder working groups. Other sources include large population-based initiatives, such as the UK Biobank (www.ukbiobank.ac.uk) and the All of Us Research Program (Sankar and Parker 2017); cohorts based on military personnel, such as the Million Veteran Program (www.mvp.va.gov/pwa); and research collaborations with large direct-to-consumer DNA testing companies, such as 23andMe (www.23andme .com/en-int). A number of Scandinavian countries now allow researchers to combine large-scale genotyping efforts with registry-based data on disease and exposure (e.g., iPsych in Denmark [Pedersen *et al.* 2018] and the Norwegian Mother, Father and Child Cohort Study [MoBa; www.fhi.no/en/studies/moba]). Another possibility is the use of electronic health records (EHRs), which are commonly used in health care systems, particularly in the United States (Dewey *et al.* 2016; Rader and Damrauer 2016). Some of these records have genomic data linked and as such provide new opportunities for population-based studies in psychiatry, with some studies already indicating good predictive value with diagnostic algorithms (Smoller 2016). The PsycheMERGE consortium was specifically formed to utilize EHRs for genetics research (Crawford *et al.* 2014).

Cross-Disorder Studies

Disorder-specific GWAS have by now identified robust genetic hits for all diagnoses, led in number by more than 200 independent genetic loci associated with schizophrenia.

It has become increasingly clear that most psychiatric disorders share genetic risks, as indicated in family studies. The genetic architecture correlation calculated from common SNPs is high (r = 0.68 for bipolar disorder and schizophrenia, r = 0.47 for bipolar disorder and depression, and r = 0.43 for schizophrenia and MDD) (Cross-Disorder Group of the Psychiatric Genomics Consortium *et al.* 2013). A study investigating the genetic overlap of brain disorders using GWAS of 265,218 patients and 784,643 control subjects observed that psychiatric disorders overall shared genetic risk, with a correlation of 0.41 across these disorders, whereas the neurological disorders were genetically more distinct from each other (Anttila *et al.* 2018).

Attempts have been made to identify the underlying molecular source of the genetic overlap across disorders (i.e., those genetic variants shared across disorders). The Cross-Disorder Group of the Psychiatric Genomics Consortium *et al.* (2013) initially examined five disorders (i.e., schizophrenia, MDD, bipolar disorder, ASD, and ADHD) in a combined sample of more than 33,000 case participants and over 27,000 control participants. Findings from these cross-disorder studies confirmed the biological overlap of psychiatric traits. Four loci with genome-wide significance for cross-disorder risk were found, including the L-type voltage-gated calcium channel subunits CACNB2 and CACNA1C, again implicating calcium channels in psychopathology. This investigation has recently been expanded to include patients with anorexia nervosa, OCD, and Tourette syndrome, for a total of more than 230,000 case participants and close to 500,000 control participants. Here, differing genetic correlations among groups of disorders were noted, with strong correlations between schizophrenia and bipolar disorder and also between anorexia nervosa and OCD, for example, but these latter two disorders are less correlated with schizophrenia and bipolar disorder. Overall, more than 100 loci are associated with at least two disorders, and more than 20 with four or more disorders, providing strong support for specific patterns of shared genetic risk (Lee *et al.* 2019).

Computational Techniques Using GWAS Summary Statistics

Polygenic Risk Scores

Already with early GWAS, it became clear that in complex disorders, genetic risk is determined both by many common variants of small effect and by rare and de novo variants of large effect.

This dilemma again illustrates the inadequacy of the "common disease, common variant" model and the limitations of GWAS. As a result, it has been proposed that between these two extremes, there is a middle ground in which moderately penetrant but somewhat rarer variants are being missed (Maher 2008). These missing variants might be unearthed if a single polygenic score or polygenic risk score (PRS) could be calculated. Polygenic analysis examines the extent to which heritability is due to the additive effects of many common loci variants that individually are of little effect (Dudbridge 2013). By using all SNPs to examine the net effect on disease risk, a composite score can be calculated, thus providing significant predictive ability. The PRS is composed of many true but subthreshold variants that GWAS initially might have missed as a result of being underpowered to detect them at the conventional alpha level of $P = 5$ x 10^{-8} (Gratten *et al.* 2014). Polygenic risk profiling from large GWAS is able to predict case-control status in independent, and also smaller, samples. The PRS also can be analyzed in relation to the clinical phenotype and against quantitative traits related to the disorder.

This approach was validated, for example, in schizophrenia (Schizophrenia Working Group of the Psychiatric Genomics Consortium 2014) and has been shown to predict schizophrenia case-control status in a number of independent samples (Meier *et al.* 2016), with risk increased up to 15-to 20-fold for individuals in the highest polygenic risk score decile. Similar approaches have been applied to other disorders. For MDD, individuals in the highest polygenic risk decile have a 2.0-to 2.5-fold increased risk (Wray *et al.* 2018). Such PRSs could be promising biomarkers to guide clinicians in diagnosis, treatment choice, and prediction of disease course. Such risk scores may also be used to identify individuals at high risk for psychiatric disease before disease onset for targeted preventions and early intervention. In fact, the use of PRSs as predictors in clinical care has been proposed for medical disorders (Khera *et al.* 2018; Lambert *et al.* 2019).

An important step for clinical application is to understand whether PRSs derived in a research setting can be applied to real-world clinical settings. Zheutlin *et al.* (2019) have explored this question by applying the PRS for schizophrenia (derived from samples collected in a research setting) to EHR data from four different health care system-based biobanks. The authors could predict psychosis and schizophrenia using the PRSs in these datasets, but with lower ORs than in studies from research settings. Individuals in the top decile of PRSs had a 2.0-to 4.5-fold increased risk. These effects sizes are comparable to those observed for medical disorders (Khera *et al.* 2018), suggesting that genetic prediction strategies may also be applied to psychiatry. Although highly statistically significant, the effects of the PRS were not sufficiently large to allow an accurate discrimination of patients.

The PRS is a promising tool, but many open questions need to be addressed before it can be applied in the clinical setting:

1. PRSs developed in one ancestral group will not directly extend to another, and so far the vast majority of GWAS have been conducted in populations of European ancestry. For example, PRSs for schizophrenia calculated based on association results in one population are significantly less predictive in another. Performing GWAS in non-European populations is a great need (Duncan *et al.* 2019) and is necessary for their application in a global clinical setting.
2. Shared genetic heritability among psychiatric and also neurological and medical disorders (Anttila *et al.* 2018) poses problems for applying PRSs as clinical tools. The schizophrenia PRS additionally associates with risk for PTSD, bipolar disorder, and other psychiatric disorders, with CIs of ORs mostly overlapping with those of ORs for schizophrenia and psychosis, and the same PRS is also associated with some medical conditions. Such pleiotropy in prediction raises issues for clinical implementation.
3. PRSs developed in one specific clinical context, such as adult patients, may not perform in other contexts (e.g., younger individuals).
4. PRSs may need to be combined with information on other risk domains to improve prediction. In medical disorders, multimodal prediction models that integrate PRSs (Lambert *et al.* 2019) perform better than those that do not. A PRS for

coronary artery disease, for example, increases the accuracy of established clinical predictors, such as the Framingham Risk Score (Abraham *et al.* 2016).

5. For medical disorders, it has been proposed that the PRS may be most useful for prevention (Lambert *et al.* 2019). In children with a family history of type 1 diabetes, for example, a PRS for this disorder was able to predict progression to diabetes before any metabolic abnormalities were present (Redondo *et al.* 2018). Such an application may be relevant for youths at high risk for psychiatric disorders and inform targeted prevention and interventions studies.

In addition to PRSs, a number of computational tools are now available to increase our understanding of genetic factors in psychiatry. These include the following:

- *Mendelian randomization*, which enables an assessment of potential causality in the association between two traits based on Mendel's law that the genetic variants associated with these traits are inherited independently, thus providing a "natural" randomized controlled trial (RCT) (for a review, see Wootton *et al.* 2022). Here one of the traits can also be molecular phenotypes, such as the effects of SNPs of immune measures, mapped to GWAS for a disease of interest (Kappelmann *et al.* 2021). This procedure allows one to test whether changes in immune function are causally related to depression, for example, via their shared genetics.
- *Transcriptome-wide association studies (TWAS)*, which combine both GWAS and gene expression datasets to understand the effect of genetic risk on the transcriptional profile of a target tissue, and thus its potential impact on function (for further detail, see Hernandez *et al.* 2021 and Wainberg *et al.* 2019).
- *Phenome-wide association studies (pheWAS)*, which allow one to explore the genetic association of a more limited number of genetic variants with a large number of phenotype datasets (e.g., EHRs), permitting detection of novel genetic overlaps of phenotypes (see Bush *et al.* 2016 and Wang *et al.* 2021).

From Association to Function--Approaches to Using the Data

While GWAS have yielded many associated loci, they do not directly allow an understanding of the underlying biology. Figure 3-3 illustrates the steps from an association study to improved functional understanding. As shown in Figure 3-3, GWAS unveil genome-wide significant loci. These are often represented in so-called Manhattan plots (Figure 3-4). In the plot in this figure, each dot represents the association strength of a single SNP, mapped to a negative log of the *P* value, so the higher the peak, the more significant the association. What becomes clear from these plots is that "towers of associations" are observed due to the above-described linkage disequilibrium.

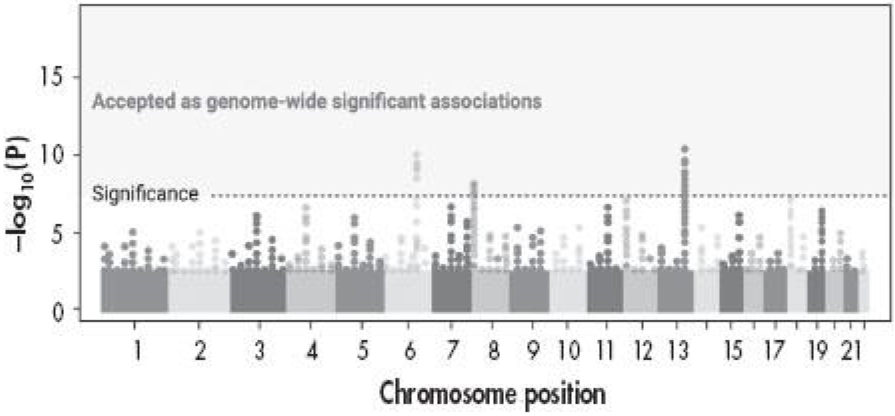

FIGURE 3-4. Manhattan plot.

A Manhattan plot is a specific scatterplot used to display genome-wide association data. Each single nucleotide polymorphism (SNP) is plotted by its position in the genome: the chromosomes of the human genome and the positions on chromosomes are plotted on the x-axis, and the significance of the association with the trait (the [?]$\log_{10}$ of the statistically significant associations) is plotted on the y-axis. The horizontal line shows the standard threshold for genome-wide significance (5×10^{-8}). SNPs are in linkage disequilibrium with the index SNPs (*diamonds*) that represent independent genome-wide significant associations. Schizophrenia was associated with 108 independent loci.

SNPs in linkage disequilibrium will all show similar associations (depicted in Figure 3-3A, panel 4, with red squares denoting high LD [i.e., high correlation of the SNP genotypes]). Depending on the size of the LD block, a single or many genes can fall under these association peaks, making it very difficult to pinpoint the gene of interest in the absence of additional information. Several steps have been proposed to close in

on the relevant genes from GWAS signals. These include mapping the association signal to molecular quantitative trait loci (QTL), mapping genes to pathways, and mapping SNPs to regulatory elements.

Mapping an association signal to molecular quantitative trait loci.

To understand whether SNPs within an association signal also influence molecular phenotypes, one can use QTL mapping (see Figure 3-3B, panel 1). Often gene expression QTL datasets are used, and many such resources are available online; these include the Genotype-Tissue Expression (GTEx) project (GTEx Consortium 2013), with genotype and RNA sequencing data from close to 1,000 donors and 54 different tissues, including 13 from brain (different brain regions and fetal brain); BrainSpan (Kang *et al.* 2011), with gene expression data from different brain structures across the life span (pre-and postnatal); and the PsychENCODE project (Wang *et al.* 2018; see also, e.g., PsychENCODE Consortium 2018). Use of QTL datasets allows one to see whether an association with disease is also linked to an association with differential gene expression in a specific tissue and, with ever-expanding single-cell sequencing data, in a specific cell type. These types of analyses can additionally be combined in the above-described TWAS. However, QTL mapping can also be performed with other molecular traits, including protein QTL and QTL related to epigenetic regulation, such as DNA methylation QTL and QTL for open chromatin or specific histone modifications (Figure 3-5) (for an in-depth discussion, see Hernandez *et al.* 2021).

This figure summarizes the different types of epigenetic modifications. **(1)** DNA modifications: Cytosines can be modified by methylation, hydroxymethylation, formylation, and carboxylation, whereas adenines can only be modified by methylation (adenylation). **(2)** Chromatin modifications: Nucleosomes, composed of DNA wrapped around histone proteins, can change position to increase or decrease DNA accessibility. Nucleosomes also can be modified by adding histone variants and posttranslational modifications. **(3)** Noncoding RNAs can regulate transcription and thus are also considered an epigenetic mechanism. **(4)** RNA modifications (epitranscriptomics): Gene expression can be influenced by RNA modifications, which are also reversible. DNMT2 = DNA methyltransferase-like protein 2; METTL3 = methyltransferase-like 3.

Mapping genes to pathways.

Once sets of genes are mapped for a given genome-wide association study, they can be explored using gene network co-expression analyses (Gandal *et al.* 2018) and tested for enrichment in known pathways.

Pathway analysis increases the power of the data because association signals are grouped by functionally related genes. Pathway analysis can provide insight into the cellular-or molecular-level pathways underlying the disorder. Gene Ontology (GO; http://geneontology.org), for example, is a publicly available online resource providing classification of gene function. There are three main categories of terms in GO: Molecular Function, Biological Process, and Cellular Component. A set of terms and their definitions and any defined relationships are set into a hierarchical structure. Each gene is described by multiple GO terms. Beyond identifying functional roles (GO terms) of gene products, *gene ontology enrichment analysis* can be used to statistically determine which terms appear more frequently than expected by chance alone. Such pathway analyses have revealed the relevance of regulation of synapse function, immune function, and also epigenetic factors in psychiatric disease (Network & Pathway Analysis Subgroup of Psychiatric Genomics 2015).

Mapping SNPs to regulatory elements. Mapping causal SNPs from GWAS is complicated by the fact that most association signals for complex disorders, including psychiatric disorders, map to gene regulatory regions, often also at a greater distance from the regulated transcripts. Gene regulatory regions are defined in their activity by epigenetic modifications that alter chromatin accessibility: these include DNA methylation as well as histone modifications (see also Figure 3-5).

DNA methylation (DNAm) regulates gene expression through direct modifications to the DNA. Nucleotides located primarily, but not exclusively, in sequences of cytosine-phosphate-guanine (CpG) dinucleotides are covalently modified (Xie *et al.* 2012). Non-CpG methylation seems to be restricted to specific cell types, such as pluripotent stem cells, and also neurons and glial cells (Jang *et al.* 2017). Increased DNAm is associated with a less accessible DNA sequence, and when this occurs in the promoter region of a gene, it is associated with decreased gene expression. Additionally, hydroxymethyl groups and other chemical DNA modifications (formyl or carboxyl groups) have been described, of which hydroxymethylation occurs preferentially in neurons (Cholewa-Waclaw *et al.* 2016; Traube and Carell 2017). Hydroxymethylation has been associated with facilitating gene transcription.

Histones are an important component of the epigenome, responsible for packaging DNA in chromatin. Histone phosphorylation, acetylation, or methylation at specific amino acid residues regulates how accessible the DNA is (i.e., how tightly or loosely wrapped the DNA is) and thus impacts gene transcription (Hsieh and Gage 2005). The addition or removal of these posttranslational changes is mediated by a number of enzymes, which include histone acetyltransferases as well as histone deactylases. Depending on the chemical reaction, these changes can either promote or inhibit gene transcription.

Using genomic datasets from ENCODE (Encyclopedia of DNA elements) (ENCODE Project Consortium 2012) and its brain-specific counterpart PsychENCODE, as well as Roadmap Epigenomics (Kundaje *et al.* 2015), one can map single SNP loci to putative enhancer elements (see Figure 3-3B, panels 2-4) that are defined by overlaying information on chromatin accessibility (e.g., using assay for transposase-accessible chromatin with sequencing [ATAC-seq]), DNA methylation, and different histone modifications that are assessed using Chromatin ImmunoPrecipitation DNA-Sequencing (Chip-seq). SNPs located within such regulatory elements are enriched among GWAS signals and more likely to be functional, and can impact gene regulation. It should be noted that gene regulatory elements can be specific not only to cell types but also to context, so that mapping in a tissue-and cell-type-specific way as well as under certain stimulation conditions (e.g., immune stimuli) will be important.

Following the mapping of SNPs to regulatory elements and genes, the next step is to infer causality, which can be done through the following processes:

1. Recent technological advances now make it possible to test for allele-specific effects of SNPs on enhancers. Massively parallel reporter assays (MPRAs) evolved from simple *reporter assays* (where a specific regulatory element is cloned into a plasmid upstream of a reporter gene, then transfected into a cell to understand the transcriptional effects of the regulatory element) (see Figure 3-3C, panel 1). The MPRA is a scaled-up version that allows many (tens of thousands) functional regulatory elements to be investigated simultaneously for each allele. These assays allow us to test for regulatory activity in a cell-type and context-specific way. For a review of the applicability of MPRA to psychiatry, see Mulvey *et al.* (2021).
2. Once specific putatively causal SNPs are identified, their effects need to be tested in a cellular context (see Figure 3-3C, panel 2). For this, the combination of CRISPR (clustered regularly interspaced short palindromic repeats)-Cas9 (CRISPR-associated protein 9) technology (which allows us to edit gene sequencing to either introduce or revert a specific genetic variant) and human induced pluripotent stem cells (hiPSCs) has opened up unprecedented possibilities. hiPSCs with specific genetic edits can then be differentiated into either three-dimensional cerebral organoids or two-dimensional brain cells, including neurons and glia, to test for the effects of the genetic variants on cell function. For this, many tools--ranging from omics over imaging to electrophysiology--are available. It is also possible to start to model the effects of multiple variants in an aggregated manner, more closely mimicking the polygenic effects observed in complex diseases (Schrode *et al.* 2019).
3. Although the advent of hiPSC-derived systems now allows us to investigate the effects of genetic variation, including patient-specific variations, on human brain

cell function, the systems are often immature. These investigations can only serve as add-ons to experiments conducted in behaving organisms. Through the use of CRISPR-based models and other tools, laboratory animals carrying human genetic variations can be generated and observed on many levels, including complex behaviors. Finally, hiPSC-derived cells can be transplanted into laboratory animals to study their function in the context of an intact brain (see Figure 3-3C, panel 3).

Gene-by-Environment Interplay

This final section introduces the environment as an important risk factor in interplay with genetic risk and also introduces epigenetics as one mechanism that could mediate gene-by-environment interplay. Trauma, chronic stress, and exposure to adverse life events are the most significant risk factors for many psychiatric disorders (Teicher *et al.* 2022). In fact, adverse life events or traumatic experiences substantially increase risk for MDD, PTSD, substance and alcohol use disorders, bipolar disorder, schizophrenia, and other disorders (Teicher and Samson 2013). Despite their importance in contributing to disease risk and disease presentation, we still have insufficient knowledge about the precise risk mechanisms, thereby limiting therapeutic approaches targeting the consequences of exposure to adversity. We know that not all exposed individuals will develop disease, suggesting underlying individual factors that moderate the relationship between exposure and disease (Elbau *et al.* 2019). Additional exposures to environmental protective or risk factors and timing and duration of the exposures, as well as genetic factors, have been hypothesized to moderate this relationship. Indeed, studies using SNP-based heritability measures suggest a genetic component that may be specific to adversity-associated psychiatric risk. In the U.K. Biobank cohort, an SNP-based heritability of 12% is evident for MDD alone and increases to 24% in patients with reported trauma (Coleman *et al.* 2020). Another study in an independent cohort demonstrates context-specific heritability for different complex traits, including gene-by-adversity effects in depression (Dahl *et al.* 2020).

Identifying the specific variants moderating the effects of adversity has proven difficult, and the investigation of such interactions at the candidate gene, genome-wide, and polygenic levels has yielded inconsistent results

(Border *et al.* 2019; Vassos *et al.* 2022). It is unclear how well such adversity-moderating genetic components could be uncovered from genome-wide interaction studies or other approaches using large cohorts. These approaches are complicated by the requirement of even larger sample sizes, as the complexities of comprehensive adversity definition and characterization (exposome) will increase heterogeneity.

A mechanism that might support the molecular embedding of gene-by-environment interactions is epigenetics (see, e.g., Aristizabal *et al.* 2020 and Klengel and Binder 2015 for reviews). *Epigenetics* refers to processes affecting gene expression and translation that do not involve changes in the DNA sequence and include DNA and RNA modifications and noncoding RNAs (ncRNAs), as well as histone modifications (see Figure 3-5). DNA methylation and histone modifications have been described above in the context of regulatory elements.

ncRNAs play a role in regulating mRNA. Long ncRNAs regulate gene expression by modifying the structure and thus stability of chromatin. Short interfering RNAs (siRNAs) mediate posttranscriptional gene silencing via RNA degradation. Micro-RNAs (miRNAs) fine-tune gene expression by targeting mRNA. miRNAs enforce their effect through direct binding to the 3' untranslated region (3'UTR) of the mRNA of their target gene, leading to an impairment of the synthesis of the encoded protein and faster degradation of the mRNA (Filipowicz *et al.* 2008; Issler and Chen 2015).

The epitranscriptome describes epigenetic changes affecting RNA. It represents another layer of epigenetic regulation that influences many aspects of RNA function, including maturation, stability, distribution, and protein translation. RNA modifications have been documented on almost all types of RNA (Boccaletto *et al.* 2018). The most common and best described RNA modification is the methylation of adenosine on mRNA to N^6-methyladenosine (Yue *et al.* 2015).

Epigenetic mechanisms are influenced by genetic (see subsection "Mapping an Association Signal to Molecular Quantitative Trait Loci" earlier in this chapter) and environmental factors (Aristizabal *et al.* 2020) and are important mechanisms for the integration of genetic and environmental risk factors to lead to changes in gene regulation. Both genetic and environmental factors can drive epigenetic processes, and these factors are not independent and have been shown to interact. Gene-by-environment interactions represent the influence of environmental and genetic factors on a measured phenotype--in this case, epigenetic modifications. In two studies of newborns (Czamara *et al.* 2019; Teh *et al.* 2014), the influence of the prenatal environment and genotype on genome-wide DNA methylation was examined and revealed combined effects of genotype and environment. Additive and multiplicative effects explained a much larger proportion of DNA methylation variation than did genotype or environment alone, supporting the importance of considering genotype in epigenetic studies.

Conclusion

In as early as 2005, Kendler pointed out that the phrase "a gene for . . ." will not apply to psychiatric genetics, noting that "the impact of individual genes on risk for psychiatric illness is small, often nonspecific, and embedded in a complex causal pathway" (Kendler 2005, p. 1243). Indeed, psychiatric disorders are polygenic in nature, with numerous genes individually contributing a small impact on risk. Today, there is little dispute as to the important role genetics plays in psychiatric disorders. As such it holds the strongest promise for uncovering the underlying pathomechanisms.

There still remain many challenges in genomics within psychiatry. Although genetic testing is recommended in patients with ASD or intellectual developmental disorder, in reality, its clinical use is still very limited. Specific guidance on genetic testing and clinical pharmacogenetics can be found in the recommendations published in a statement by the International Society of Psychiatric Genetics (2019). However, despite pharmacogenomic testing (and guidelines for its use) being widely available, its utility has not yet been clearly established. One final goal for the use of genomics in psychiatry is to deliver personalized medicine (Figure 3-6). Given the likely future impact this field will have on clinical care, it can be argued that the education of genetic principles in psychiatry should be at the forefront of training. Next-generation sequencing will soon become clinically relevant; therefore, the use of genetic counseling in psychiatry is essential and should become an integral part of psychiatric training (Nurnberger *et al.* 2018).

CHAPTER 4

Psychoneuroendocrinology

Luca Sforzini, M.D.
Frances Isabella Weston, B.Sc.
Carmine Maria Pariante, M.D., Ph.D., FRCPsych

The neuroendocrine system is the major route of communication between body and mind. It results from the interaction between the endocrine system and the nervous system (Toni 2004). These two systems interact through different chemical signs--hormones for the endocrine system and neurotransmitters for the nervous system--to maintain the homeostasis, that is, the equilibrium between every single component of the body. Given the strong connection between body and mind, an alteration in homeostasis could be both a cause and a consequence of mental illnesses. Psychoneuroendocrinology studies exactly this, the bidirectional connection between the neuroendocrine system and psychiatric symptoms. Growing research has revealed how neuroendocrine dysregulations are frequently associated in a bidirectional link with different psychiatric conditions, including major depressive disorder (MDD) (Belvederi Murri *et al.* 2014), bipolar disorder (Daban *et al.* 2005), psychotic disorders (Rutigliano *et al.* 2020), and trauma-and stress-related disorders (D'Elia *et al.* 2021). In this chapter, we aim to examine the evidence on psychoneuroendocrinology. We first describe the physiology of the neuroendocrine system. We then focus on the role of this system in psychiatric disorders and discuss the clinical relevance of this relationship.

Physiology of the Neuroendocrine System

The neuroendocrine system consists of four major elements: the hypothalamic-pituitary-adrenal (HPA), hypothalamic-pituitary-thyroid (HPT), and hypothalamic-pituitary-gonadal (HPG) axes and the hypothalamic-neurohypophyseal system. All the "axes" (HPA, HPT, and HPG) operate in a similar way. The hypothalamus is the coordinating center, with numerous peripheral and central inputs and a major output toward the pituitary gland, or *hypophysis*. Indeed, hypothalamic neurohormones are also called *releasing hormones* because of their ability to regulate the secretion of hormones from the anterior pituitary (or *adenohypophysis*). Finally, pituitary hormones stimulate hormone production in peripheral glands. An important feature of the neuroendocrine system is the negative feedback loop by which each axis self-regulates its own hormone production. Hormones produced at a peripheral level act upstream from the axis, inhibiting the release of the respective hypothalamic and pituitary hormones. The hypothalamic-neurohypophyseal system operates in a slightly different way. Hypothalamic neurons and their axonal projections cause the release of hormones from the posterior pituitary (or *neurohypophysis*) to the bloodstream. Readers interested in a more detailed discussion of the neuroendocrine system and its role in mood disorders are referred to the chapter by Sforzini and colleagues in *The American Psychiatric Association Publishing Textbook of Mood Disorders*, Second Edition (Sforzini *et al.* 2022). Figure 4-1 schematically outlines the physiology of the neuroendocrine system.

Schematic representation of the four major neuroendrocrine elements: the hypothalamic-pituitary-adrenal (HPA), hypothalamic-pituitary-thyroid (HPT), and hypothalamic-pituitary-gonadal (HPG) axes and the hypothalamic-neurohypophyseal system (HNS). Hypothalamic neurons produce releasing hormones and HNS hormones. Releasing hormones act on the anterior pituitary gland, causing the release of stimulating hormones. HNS hormones are released from hypothalamic axons in the posterior pituitary, or neurohypophysis. The stimulating hormones produced in the pituitary gland stimulate peripheral organs (thyroid, gonads, and adrenal cortex) to produce specific hormones, which in turn exert several biological functions (T_3, T_4; testosterone, progesterone, estrogens; and cortisol, respectively). These peripheral hormones can act backwards within each axis, self-controlling their production in a negative feedback loop. The HPT axis is represented in *yellow*; the HPG in *red*; the HPA in *green*; the hypothalamus and HNS in *blue*; and the pituitary gland in *light blue*. *Arrows* indicate stimulation, and *dotted lines* indicate inhibition. Hormone-producing organs are described in *rounded boxes*, and hormonal products are depicted as *rectangles*. ACTH = adrenocorticotropic hormone; AVP = arginine vasopressin; CNS = central nervous system; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; OT = oxytocin; T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is a key immune modulator and the main component of the stress response, together with the autonomic nervous system (ANS) (Ulrich-Lai and Herman 2009). In response to stressful and potentially harmful stimuli, our body reacts with multifaceted biological effects intended to promote the fight-or-flight response. The ANS represents the most rapid response, while the HPA axis is responsible for more complex and both acute and longer-term biological modifications, modulating homeostasis in the whole body.

Neurons of the paraventricular nucleus (PVN) of the hypothalamus produce corticotropin-releasing hormone (CRH), leading to the release of adrenocorticotropic hormone (ACTH) in the anterior pituitary. ACTH stimulates the cortical region of the adrenal glands, which are two endocrine glands located on top of the kidneys. The final products of the HPA axis are glucocorticoid hormones, mainly cortisol in humans (see Figure 4-1). Glucocorticoids are steroid hormones, synthesized from cholesterol, that are capable of passing through cells' lipidic membranes and acting on nuclear receptors. Cortisol levels change in accord with the circadian rhythm. They reach their highest levels in the morning shortly after awakening (usually around 8 A.M.), in what is known as the *cortisol awakening response* (CAR) (Elder *et al.* 2014); they then progressively decline, reaching the lowest level during the night, about 3-5 hours after falling asleep (roughly from midnight to 4 A.M.).

There are two different types of receptors for glucocorticoids: glucocorticoid receptors (GR), encoded by *NR3C1* (the nuclear receptor subfamily 3, group C, member 1 gene), and mineralocorticoid receptors (MR). Cortisol binds to GR with low affinity and to MR with high affinity.

This finding supports the hypothesis that MR binding is mainly involved in the homeostatic basal function, whereas cortisol-GR binding is more clearly related to stress response, when cortisol levels are increased (Pariante 2004). GR is therefore the main modulator of HPA axis activity. It is necessary for life after birth and is expressed in nearly every cell of the body. Following glucocorticoid binding, GR regulates the transcription of target genes and mediates composite biological actions (Oakley and Cidlowski 2013). The gene *FKBP5*, encoding FK506-binding protein 51 (FKBP51), a co-chaperone protein, is central in GR functioning and sensitivity (Alhajji and Nemeroff 2015). FKBP51 physiologically binds to the GR complex, reducing the receptor affinity for glucocorticoid. Following the activation of GR by glucocorticoids, transcription and translation of *FKBP5* are increased, and this reduces the GR sensitivity in an ultra-short negative feedback loop (Binder 2009; Menke 2019).

The production of glucocorticoids is finely regulated. Similar to what we will discuss for other components of the neuroendocrine system, under physiological conditions cortisol inhibits the synthesis of CRH/ACTH by exerting negative feedback (see Figure 4-1) (Zunszain *et al.* 2013). Notably, GR mediates this negative feedback. Thus, when GR is disrupted, such as in chronic glucocorticoid stimulation, the negative feedback is impaired. This phenomenon is called *glucocorticoid resistance* and in turn leads to HPA axis hyperactivity (Pariante and Lightman 2008; Pariante and Miller 2001). Suppression tests evaluate the efficacy of the negative feedback mechanism. They are the most diffused clinical tests to evaluate the HPA axis. Cortisol levels are measured after the injection of exogenous steroids, such as dexamethasone, which binds to GR, in the dexamethasone suppression test, and prednisolone, which probes both GR and MR (Juruena *et al.* 2009), in the prednisolone suppression test.

Hypothalamic-Pituitary-Thyroid Axis

The HPT axis is crucial in regulating metabolism, influencing basal metabolic rate, energy balance, protein synthesis, and cell growth. The hypothalamic thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH). TSH induces the thyroid, an endocrine gland located in the anterior part of the neck, to produce the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4), together with the peptide hormone calcitonin (see Figure 4-1). T_4 is mainly released into the bloodstream and then enzymatically converted to T_3. T_3 has much higher affinity for the thyroid hormone nuclear receptor (TR) (Baek *et al.* 2014). Under pathological conditions, thyroid functioning could be increased (hyperthyroidism) or reduced (hypothyroidism). In addition, TSH levels may be altered (increased or reduced) in the presence of normal levels of thyroid hormones (subclinical hyperand hypothyroidism, respectively). As described for the HPA axis, T_3 and T_4 inhibit TRH and TSH secretion via negative feedback (see Figure 4-1).

Hypothalamic-Pituitary-Gonadal Axis

The HPG axis is the principal modulator of the reproductive system. The hypothalamic gonadotropin-releasing hormone (GnRH) stimulates the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (see Figure 4-1). These two hormones act on the gonads with different and precise functions. In females, they promote the ovarian production of estrogen and progesterone, regulating menstrual and ovarian cycles. In males, they chiefly induce the testicular production of testosterone, regulating spermatogenesis. Again, sex hormones could inhibit their own production by acting on the hypothalamus or hypophysis in a negative feedback loop (see Figure 4-1). Estrogens and testosterone are largely bound to carrier proteins, mainly albumin and sex hormone-binding globulin, and only in a very small percentage (approximately 1%-2%) they are unbound--so-called free--

and bioactive. Remarkably, estrogens widely change their levels in relation to life stages and menstrual and ovarian cycles. Testosterone levels can vary, even if less intensely, according to one individual's age. Notably, though, androgen levels may also vary within the same day, similarly to cortisol levels, with significant diurnal variation (Long *et al.* 2015). Sex hormones act on specific nuclear receptors. There are two main types of estrogen receptors, alpha (ER-a) and beta (ER-b) receptors, and one androgen receptor. The progesterone receptor has two main isoforms (PR-A and PR-B), which differ in molecular weight (Jacobsen and Horwitz 2012). Sex hormone receptors are nuclear, similar to GR, MR, and TR.

Notably, there is a mutual connection between the HPG and HPA axes. Increased glucocorticoid levels inhibit GnRH and gonadotropins levels, while sex hormones regulate levels of cortisol (Toufexis *et al.* 2014). As an example, Cushing's syndrome is frequently associated with amenorrhea (Zada *et al.* 2015). In addition, HPA axis hypoactivity may result in chronically high testosterone levels (Ludwig *et al.* 2019).

Hypothalamic-Neurohypophyseal System

The hypothalamic-neurohypophyseal system involves the posterior pituitary, or neurohypophysis. This system is different from systems in the anterior pituitary, because it does not produce hormones directly, but instead includes axonal projections of hypothalamic neurons. Hypothalamic neurons produce two structurally related hormones, oxytocin and vasopressin (or arginine vasopressin, AVP), which are then released into the neurohypophyseal capillaries and from there into the bloodstream (see Figure 4-1). Oxytocin facilitates parturition and lactation by acting on uterus smooth muscles and mammalian glands. Interestingly, it additionally plays a significant role in social functioning (Jones *et al.* 2017), where it promotes affiliation and both mother-child and pair bonding and modulates fear and anxiety behavior (Zik and Roberts 2015). AVP regulates body water balance and fluid homeostasis and chiefly regulates blood pressure, osmotic balance, and kidney function. Therefore, it is also called *antidiuretic hormone* (ADH). Under pathological conditions, the release of AVP can be increased, as is observed in the syndrome of inappropriate ADH secretion (SIADH), or decreased, causing diabetes insipidus (Verbalis 2014). AVP acts on three different receptors: V_{1a}, V_{1b} (also known as V_3), and V_2 (Surget and Belzung 2008). On the other hand, oxytocin has a unique receptor. Notably, oxytocin and AVP and their receptors show high homology, potentially accounting for signaling crosstalk (Rae *et al.* 2022). Also, both neurohypophyseal hormones can affect the HPA axis activity (Engelmann *et al.* 2004). Particularly, AVP is a main regulator of the HPA axis. It modulates the secretion of ACTH and is possibly involved in HPA hyperactivation--mainly through the V_{1b} receptor--under stress conditions (Goncharova 2013).

Immune-Neuroendocrine Interactions

The immune system and its response, inflammation, are strongly connected to both the neuroendocrine system and psychiatric disorders. They are, therefore, important factors in the relationship we are debating in this chapter. Inflammation has been consistently associated with the pathophysiology of several psychiatric diseases, including mood (Pariante 2017; Stetler and Miller 2011), psychotic (Kose *et al.* 2021), and stress-related disorders (Heim 2020; Sumner *et al.* 2020). In addition, compelling evidence has demonstrated complex immune-neuroendocrine crosstalk (Ashley and Demas 2017). Immune cells can produce low levels of different hormones, and neuroendocrine cells can release inflammatory cytokines (Verburg-van Kemenade *et al.* 2017). In this section, we briefly discuss the main interactions between the neuroendocrine system and the immune processes.

The HPA axis is the most important component in immune-neuroendocrine interactions, being strongly and bidirectionally connected with the immune system. It modulates the inflammatory responses that occur throughout the whole body, including the CNS (Otmishi *et al.* 2008). Cortisol has an extremely powerful anti-inflammatory effect and can be activated by several proinflammatory cytokines, such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor alpha (TNF-a). In addition, immune cells express both GR and adrenergic receptors (Menard *et al.* 2017). Hyperactivation of the HPA axis, which is typical of chronic stress conditions (such as chronic illnesses), can induce persistent glucocorticoid resistance. The related absence of GR-mediated negative feedback leads to HPA axis hyperactivity, and, at the same time, the absence of GR-mediated restraint of inflammation leads to increased inflammation (Pariante 2014). In a recent meta-analysis testing the association between glucocorticoid resistance and increased inflammation in depression, Cattaneo *et al.* (2020) found limited evidence for a positive association between glucocorticoid resistance and inflammation. In addition, despite the presence of increased inflammatory biomarkers and reduced GR messenger RNA (mRNA) expression in the MDD patients analyzed, the Biomarkers in Depression (BIODEP) study similarly found unclear evidence for a correlation between inflammatory biomarkers, GR mRNA expression, and salivary cortisol levels (Cattaneo *et al.* 2020). Therefore, the "glucocorticoid resistance model" may not be the only one explaining the complex relationship between glucocorticoid resistance and inflammation, suggesting a need for further research (Perrin *et al.* 2019).

Glucocorticoids may also have proinflammatory properties. Horowitz *et al.* (2020) showed that the administration of dexamethasone before an immune challenge enhanced the inflammation in human hippocampal progenitor cells in vitro and upregulated multiple innate immune genes. Therefore, there is also evidence of an altered glucocorticoid resistance model, in which cortisol acts as a proinflammatory mediator. An excess of cortisol may also stimulate the inflammation-related kynurenine pathway (Menke 2019). This pathway is activated during inflammation and in several psychiatric conditions, including depression (Sforzini *et al.* 2019) and schizophrenia (Kindler *et al.* 2020). Therefore, it has been proposed as a potential biological shared mechanism for psychiatric disorders comorbid with immune-related diseases.

The immune system is related to the HPT axis as well (Masek *et al.* 2003). Thyroid is essential to the normal development of the thymus, a specialized organ of the immune system. Here, thymocytes, which are hematopoietic precursors from bone marrow, mature into T-lymphocytes. This relationship is again bidirectional; activated immune cells can synthesize and secrete small quantities of TRH (Masek *et al.* 2003). In addition, the thyroid is an organ often affected by autoimmune disorders

(McLeod and Cooper 2012). Autoimmunity is a process by which an individual's immune system is activated against its own healthy components. In the thyroid, three different proteins can be targeted by three specific autoantibodies, which are directed against thyroid peroxidase, thyroglobulin, and TSH receptors. Autoimmune thyroiditis can cause both hyperand hypothyroidism, depending on the target and the stage of the illness.

The HPG axis and the hypothalamic-neurohypophyseal system have a similar and bidirectional link with the immune system. Immune cells express both estrogen (ER-a and ER-b) and androgen receptors (Taub 2008). Also, inflammatory cytokines, such as IL-1, can stimulate the release of both AVP and oxytocin (Landgraf *et al.* 1995).

Role of the Neuroendocrine System in Psychiatric Disorders

Under physiological conditions, our body and mind can face even massive perturbations and maintain homeostasis. An appropriate response to stress requires effective neuroendocrine and immune systems (McEwen *et al.* 2015; Ulrich-Lai and Herman 2009). Disruptions at any level within the neuroendocrine system could result in severe consequences for the individual's health, including mental health; conversely, the neuroendocrine system may be altered as a consequence of different psychiatric diseases (Van Dammen 2021). We now discuss the main interconnections between the neuroendocrine system and different mental disorders, categorized, following the DSM-5 classification (American Psychiatric Association 2013), as "depressive disorders," "bipolar and related disorders," "schizophrenia spectrum and other psychotic disorders," and "trauma-and stressor-related disorders."

Depressive Disorders

HPA Axis

The HPA axis mediates between stress responses and brain functioning (Pariante and Lightman 2008) and is highly interconnected with depressive disorders. Indeed, HPA axis hyperactivity is probably the most prominent and consistent neuroendocrine abnormality found in depression (Min *et al.* 2012; Pariante and Lightman 2008). HPA hyperactivity has also been proposed as a factor in the high prevalence of comorbid medical illnesses during depression (Stetler and Miller 2011). In addition, depressed patients frequently have altered responses to the dexamethasone suppression test and reduced GR mRNA expression (Palazidou 2012). A large meta-analysis confirmed this evidence of HPA axis hyperactivity in depressed individuals (Stetler and Miller 2011). The authors demonstrated that depressed individuals had significantly increased levels of cortisol (54 studies on 18,374 individuals) and ACTH (96 studies on 3,812 individuals) compared with healthy subjects. On the other hand, CRH levels were not significantly different and tended to be higher in the depressed group only when assessed in blood, but lower when assessed in CSF. Even though these effects were not significant, they may suggest a different physiological meaning of CRH levels in blood and CSF.

The degree of HPA hyperactivity varied across depression phenotypes, being the most marked in older hospitalized individuals and in depression with melancholic or psychotic features (Stetler and Miller 2011). So, notably, clinical features such as depression specifiers or age could influence HPA abnormalities. A recent study confirmed

increased cortisol levels in patients with depression with psychotic features compared with healthy subjects and with patients with nonpsychotic depression (Cherian *et al.* 2019). Moreover, Lamers *et al.* (2013) confirmed that specifiers of depression may be associated with different biological correlates. They observed that subjects with depression with melancholic features had a hyperactive HPA axis compared with control subjects. On the other hand, patients with atypical features presented a lower diurnal slope compared with control subjects and subjects with melancholic depression

(Lamers *et al.* 2013). In a recent systematic review, Agustini *et al.* (2019) analyzed patients with depression with a seasonal pattern. They found attenuated CAR during winter--but not in summer--in these patients compared with healthy control subjects, even though evidence on this specifier is still scarce. In their meta-analysis, Belvederi Murri *et al.* (2014) found significantly higher cortisol levels in elderly depressed patients (older than 60 years) compared with healthy control subjects, and this effect was even higher when postdexamethasone cortisol levels were analyzed. As the authors suggested, these higher levels could be due to different mechanisms related to aging and thus not directly related to depression.

Sex also may contribute to HPA dysfunction in depression. As an example, Sanches *et al.* (2013) found significantly higher cortisol levels in depressed patients compared with healthy control subjects, but only in males. However, evidence to date is still inconclusive. Women in the perinatal period, including both pregnancy and the postpartum period, are at higher risk of developing depression (Sawyer *et al.* 2019). The HPA axis is typically hyperactivated during physiological pregnancy. The placenta produces CRH, GR function is reduced, and glucocorticoid resistance develops (Glynn *et al.* 2013). Notably, these alterations are enhanced when depressive symptoms co-occur (Katz *et al.* 2012; Pariante 2014). During the postpartum period, CRH levels drop, with subsequent decreases in ACTH and cortisol levels. This HPA "refractory period" is a vulnerable period for the development of depression and may persist for weeks, months, or even years (Dickens and Pawluski 2018; Glynn *et al.* 2013). Furthermore, depression during pregnancy is associated with increased cortisol response to stress in offspring at 1 year of age (Osborne *et al.* 2018).

HPA alterations may mediate and predict the development of depression, being a risk factor for depression and not simply a consequence or epiphenomenon of it (Pariante and Lightman 2008). Hardeveld *et al.* (2014) demonstrated that increased CAR was associated with time to recurrence of depression and not dependent on stress-related factors. In contrast, Tsuru *et al.* (2013) analyzed patients hospitalized for depression and found no correlation between baseline HPA markers (combined dexamethasone/CRH levels) and recurrence of depressive symptoms within 10 years. HPA alterations could also predict response to antidepressant treatments. In a placebo-controlled study examining HPA axis response to a prednisolone suppression test administered to individuals with severe depression prior to receiving intensive multimodal inpatient treatment, Juruena *et al.* (2009) found higher cortisol levels and a lower percentage of suppression in patients who were subsequent nonresponders to inpatient treatment compared with those who were responders.

Finally, the HPA axis can also be chronically activated by early-life stress, including childhood maltreatment (Cousins and Goodyer 2015). This sustained hyperactivation may be an independent factor predisposing to the development of depression during adolescence and adulthood (Cousins and Goodyer 2015; Pariante and Lightman 2008; van Bodegom *et al.* 2017). Notably, the GR gene is susceptible to epigenetic modification, specifically DNA methylation (Smart *et al.* 2015). Additionally, Normann and Buttenschon (2020) have found significant HPA axis gene-environment interactions between *CRHR1*, *FKBP5*, *NR3C1*, *NR3C2,* and childhood maltreatment. Early life adversity may also influence the HPA axis during pregnancy, with greater CAR, and moderate the effect of depression on diurnal slope (Epstein *et al.* 2020).

Also crucial in the relationship is the GR complex, particularly the gene *FKBP5*. Different *FKBP5* single-nucleotide polymorphisms (SNPs) (rs1360780, rs3800373, rs4713916, rs9296158, rs9394309, rs9470080) have been significantly associated with MDD (Lekman *et al.* 2008; Szczepankiewicz *et al.* 2014) and with an increased recurrence of depressive episodes (Binder *et al.* 2004). In addition, significantly higher *FKBP5* mRNA levels have been reported in MDD patients compared with control subjects (Cattaneo *et al.* 2013) and are seen in both the hippocampus (Mamdani *et al.* 2015) and the frontal cortex (Tatro *et al.* 2009). This evidence suggests that certain GR complex polymorphisms may cause a baseline difference in GR sensitivity, increasing GR resistance and decreasing efficiency of negative feedback on the HPA axis, thereby increasing MDD risk. Notably, *FKBP5* SNPs (e.g., rs1360780) have also been associated with antidepressant response, remission, and resistance (Fabbri *et al.* 2018; Stamm *et al.* 2015). These variations may explain why HPA axis dysregulation has been seen prior to a depressive episode and can predict development of depressive symptoms or the response to treatments. Interestingly, gene-environment interactions have also been implicated in GR alterations in MDD. In a study evaluating *FKBP5* polymorphisms (rs3800373, rs9296158, rs1360780, rs9470080) in preschool children, minor allele carriers of the SNPs had significantly increased risk of developing MDD if exposed to adverse life events compared with homozygous carriers of the major allele (Scheuer *et al.* 2016). This increased risk was observed only in individuals exposed to mild to moderate adverse events, rather than severe. Further research corroborated these findings, showing that adolescent carriers of *FKBP5* SNPs (rs3800373, rs1360780) who had also undergone moderate early-life stress had increased risk of MDD (Piechaczek *et al.* 2019). An increased risk of MDD is also present in adolescent carriers of *FKBP5* SNPs (rs3800373, rs9296158, rs9470080) who have undergone sociodemographic stress. Kang *et al.* (2020) reported significant interaction effects between *FKBP5* SNPs (rs3800373, rs1360780, rs4713916) and childhood physical abuse. Individuals with the minor alleles of the SNPs showed higher depression scores compared with noncarriers when exposed to abuse. It is important to remark that these SNPs alone had no significant effect on the risk of MDD, because exposure to early-life stress was crucial (Kang *et al.* 2020; Piechaczek *et al.* 2019). Therefore, minor alleles of the *FKBP5* polymorphisms act as risk alleles, increasing susceptibility to the pathogenic effects of environmental factors, such as childhood abuse, on the development of MDD.

HPT Axis

HPT axis abnormalities are frequent in depressive disorders (Fountoulakis *et al.* 2006; Nemeroff and Evans 1989). The HPT axis generally appears to be hypoactive (Swaab *et al.* 2005) and may be disrupted at different levels. Alterations can be both central (hypothalamic and pituitary), with reduced TSH secretion (Duval *et al.* 2021) and increased TRH activity, and peripheral (in the thyroid), with elevated T_4 levels, low T_3 levels, and positive antithyroid autoantibodies (Hage and Azar 2012).

Serotonin is critical in HPT axis regulation, mainly inhibiting TRH secretion. Hence, the serotonin depletion typical of depression may be linked with increased secretion of TRH and blunted TSH response (Duval *et al.* 2002). However, most individuals with depression have no overt abnormalities in thyroid function, even though they probably have a greater prevalence of subclinical hypothyroidism compared with the general population (Bauer *et al.* 2008). Notably, Brouwer *et al.* (2005) reported higher TSH levels in depressed outpatients compared with matched control subjects, suggesting an opposite dysregulation of the HPT axis. Interestingly, Tsuru *et al.* (2013) found significantly higher TSH responses to TRH in patients whose depression recurred over a 10-year period after remission.

This relationship is bidirectional, and depression is frequently comorbid with thyroid illnesses. Hypothyroidism is the most consistently related with depression, but there is evidence for hyperthyroidism as well (Bauer *et al.* 2008). In subclinical hypothyroidism, findings are more debated. In their meta-analysis, Zhao *et al.* (2018) noticed this association only in younger patients. On the other hand, Medici *et al.* (2014) found that low TSH levels, but still within the normal range, were related to future development of depression in elderly patients. In a cross-sectional study on MDD patients, Shen *et al.* (2019) found higher serum TSH, anti-thyroglobulin antibodies, and thyroid peroxidase antibodies in individuals who had attempted suicide compared with individuals who had not attempted suicide. Thyroid peroxidase antibodies have been extensively associated with depression, also in specific clinical subgroups such as postnatal depression (Wesseloo *et al.* 2018) and subclinical hypothyroidism (Juceviciute *et al.* 2019). However, some studies did not find associations between thyroid peroxidase antibodies and depression, but did find higher concentrations of TSH receptor antibodies in depressed patients compared with control subjects (Fam *et al.* 2015). Lastly, a preclinical study found that mice with receptor-mediated hypothyroidism--caused by an unliganded TRa_1--presented a depressive phenotype, which was responsive to T_3 substitution (Pilhatsch *et al.* 2010).

HPG Axis

Growing research focuses on the role of sex hormones in mental health (Lombardo *et al.* 2021). Depressive disorders are more prevalent in women, particularly during the reproductive years (Salk *et al.* 2017). Sex hormones may therefore be involved in the pathogenesis of depression. However, a clear correlation has yet to be established (Brummelte and Galea 2016; Hammarstrom *et al.* 2009). Additionally, a recent meta-analysis found a significant association between female depression and higher serum testosterone (absolute standardized mean difference) (Maharjan *et al.* 2021). Estrogens regulate the synthesis, metabolism, receptor concentration, and trafficking of serotonin, dopamine, and norepinephrine, neurotransmitters greatly involved in depression. In addition, they regulate neuroplasticity by altering brain-derived neurotrophic factor (BDNF) levels (Schiller *et al.* 2016). An imbalance in testosterone levels has also been associated with increased risk for depression, in both sexes (Rohr 2002). Lower testosterone levels--mainly free--have been reported in males with depression (Almeida *et al.* 2008). A recent meta-analysis confirmed significantly lower testosterone levels in depressed men compared with control subjects (Fischer *et al.* 2019a). Additionally, depressed men have significantly lower estradiol levels compared with control subjects (Arinami *et al.* 2021).

Clearly, perinatal depression concurs with massive physiological alterations of sex hormones. Estrogen and progesterone levels dramatically rise and fall during pregnancy and postpartum. Both estrogens and androgens during pregnancy are involved in the development of mental changes in the postpartum period (Parizek *et al.* 2014). Furuta *et al.* (2013) demonstrated how an estrogen-mediated mechanism, mainly involving ER-a, may attenuate the onset of depressive-like behaviors in postpartum rats. Guintivano *et al.* (2014) identified epigenetic alterations in estradiol-mediated signaling genes that are implicated in postpartum depression, using combined mouse and human data.

Premenstrual dysphoric disorder (PMDD) is another important clinical condition that may affect women of reproductive age. Women with PMDD may have a higher sensitivity to changes in sex hormones, mainly the fall in progesterone levels, experiencing affective symptoms during the luteal phase of the menstrual cycle (with complete inter-episodic remission). Selective serotonin reuptake inhibitors (SSRIs) are rapidly effective in this disorder, and this may be due to their action on sex hormones, neuromodulating estrogen or progesterone levels (Lanza di Scalea and Pearlstein 2017; Yonkers and Simoni 2018).

Hypothalamic-Neurohypophyseal System

Hypothalamic-neurohypophyseal system hormones have also been studied in depression. AVP has been demonstrated to influence several CNS-related functions, including cognitive and behavioral ones (Surget and Belzung 2008). It has also been hypothesized to have a depressogenic effect. In fact, higher AVP plasma levels (van Londen *et al.* 1998) and increased AVP mRNA expression (Meynen *et al.* 2006) have been reported in depressed patients compared with control subjects. Interestingly, a major SNP haplotype of AVP receptor has been found to be protective against recurrent MDD (van West *et al.* 2004). In addition, AVP stimulates ACTH production synergistically with CRH, thus activating the HPA axis (Salata *et al.* 1988); this has been proposed as a main depressogenic mechanism (Neumann and Landgraf 2012).

Oxytocin may also be involved in the development or maintenance of depression (McQuaid *et al.* 2014). Decreased oxytocin levels have been associated with depression (Lach *et al.* 2018). In addition, perinatal depression has been linked to oxytocin levels, in a reciprocal link: low oxytocin levels during pregnancy are associated with risk of postnatal depression, and antenatal depression is associated with low oxytocin levels after birth (Sawyer *et al.* 2019). Epigenetic studies showed that DNA methylation in the oxytocin receptor gene was associated with postpartum depression (Kimmel *et al.* 2016), and specifically with persistent symptoms (King *et al.* 2017). Oxytocin may differently regulate HPA axis activity by inhibiting basal HPA axis activity and potentiating it under conditions of stress (Neumann *et al.* 2000).

Bipolar and Related Disorders

HPA Axis

Compelling research suggests that bipolar disorders may be associated with hyperactivation of the HPA axis (Daban *et al.* 2005). When bipolar and related disorders are being evaluated, it is necessary to consider that neuroendocrine alterations may differ accordingly to the phase of the disease (manic, major depressive, or mixed episode). These phase-specific alterations complicate research. Subjects with bipolar disorder, in both manic and depressive phases, have a significantly increased ACTH response to the combined dexamethasone/CRH suppression test compared with control subjects (Schmider *et al.* 1995). Also, patients with bipolar disorder whose disorder is in remission have an increased cortisol response to the dexamethasone/CRH test (Watson *et al.* 2004). A comprehensive meta-analysis (Belvederi Murri *et al.* 2016) endorsed these findings. Subjects with bipolar disorder displayed significantly higher ACTH and cortisol levels at awakening, and, similarly, when measured over 12 or 24 hours, compared with control subjects (Belvederi Murri *et al.* 2016). van den Berg *et al.* (2020) found elevated hair cortisol concentration in bipolar disorder patients compared with control subjects, with a significant peak in hair cortisol in the months prior to a manic episode. Feng *et al.* (2019) measured neuroendocrine function in untreated newly diagnosed patients with MDD and with bipolar disorder. The authors demonstrated a hyperactive HPA axis (higher ACTH and cortisol levels) in patients with MDD compared with those with bipolar disorder. These findings corroborate a potential difference between unipolar and bipolar depression, as well as a difference in neuroendocrine functioning. From a clinical point of view, both melancholic and atypical symptoms are common in bipolar depression (Belvederi Murri *et al.* 2016). As discussed, these specifiers correlate with opposing biological HPA effects (Lamers *et al.* 2013).

GR is a crucial mediator of this relationship. Research demonstrated decreased levels of GR protein (Bei *et al.* 2009), or GR-a mRNA (Matsubara *et al.* 2006), in subjects with bipolar disorder. Decreased GR-a mRNA was also identified in healthy first-degree relatives of patients with bipolar disorder (Matsubara *et al.* 2006). GR alterations in bipolar disorder have also been linked to irregular transcriptional activity and splicing (Bei *et al.* 2009; Watanuki *et al.* 2008), altered heat shock proteins (Bei *et al.* 2013), and epigenetic modulation of *FKBP5* (Fries *et al.* 2015).

As seen for depression, HPA abnormalities might also influence and predict the development of bipolar disorder and vice versa. In a 3-year follow-up study in young adults, previously high mean daytime cortisol levels significantly predicted the development of both depression and bipolar disorder (Ellenbogen *et al.* 2011). Another study showed that subjects with bipolar disorder with more previous episodes (manic or depressive) had higher mean cortisol levels and a blunted response and flatter diurnal slopes compared with those with fewer previous episodes (Havermans *et al.* 2011). These results have similarly been seen for hair cortisol concentration, which is positively associated with the number of prior mood episodes in patients with bipolar I disorder (van den Berg *et al.* 2020).

Finally, offspring of parents with bipolar disorder were found to have higher salivary cortisol levels compared with offspring of parents with no mental health disorder, independent of confounders such as medication or differences in diagnosis, but sex was not accounted for (Ellenbogen *et al.* 2004, 2010). Findings are not univocal, and there is also evidence of no significant difference in cortisol levels between the offspring of patients with bipolar disorder and offspring of healthy control subjects (Deshauer *et al.* 2006).

HPT Axis

HPT alterations have been reported in subjects with bipolar disorder (Barbuti *et al.* 2017). For example, significantly decreased free and total T_3 and TSH levels and increased free T_4 levels have been reported in unmedicated patients with bipolar II disorder (Lai *et al.* 2021). Interestingly, individuals with bipolar disorder seem to be particularly vulnerable to variations in thyroid function within the normal range, and HPT hypofunction may predict slower treatment response in bipolar depression (Cole *et al.* 2002). Hypothyroidism, with high TSH levels, is a frequent finding in bipolar disorder (Ezzaher *et al.* 2011), and it has been related to more severe features, such as rapid cycling (Bauer *et al.* 1990). Moreover, increased TSH is associated with increased risk of manic relapse (Amann *et al.* 2017), and low T_4 is associated with increased severity of mania and mood instability (more mood episodes, both manic and depressive) (Frye *et al.* 1999). TSH levels in people with bipolar depression are higher than the levels measured in study participants with unipolar depression or with schizophrenia (Wysokinski and Kloszewska 2014). In addition, patients with bipolar disorder have shown higher mean thyroid volumes (Ozsoy *et al.* 2010) and increased T_3 levels (Krishna *et al.* 2013) in comparison with healthy control subjects. These findings suggest that an imbalance in the HPT axis, either hypoactivation or hyperactivation, may be related to all phases of bipolar disorder.

As we will discuss later, treatment with lithium is well known to cause hypothyroidism, altering thyroid functionality and volume. However, lithium-naive patients with bipolar disorder also show abnormalities. Lithium-free bipolar patients show higher mean thyroid volumes and lower T_4 levels compared with control subjects (Ozsoy *et al.* 2010). Furthermore, Kraszewska *et al.* (2019) demonstrated that the percentage of hypothyroidism in lithium-treated and untreated patients was similar, suggesting changes within the HPT axis may possibly be directly related to bipolar disorder.

As seen in unipolar depression, thyroid peroxidase antibodies are frequently elevated in subjects with bipolar disorder (Bocchetta *et al.* 2016). Besides thyroid peroxidase antibodies, thyroglobulin antibodies have been demonstrated to be elevated in individuals with bipolar disorder compared with healthy subjects (Barbuti *et al.* 2017). Most of these findings were observed in those with certain bipolar disorder specifiers: in rapid cycling, with mixed features, or in bipolar depression. In a twin study (Vonk *et al.* 2007), subjects with bipolar disorder had significantly higher levels of thyroid peroxidase antibodies compared with their nonbipolar co-twins. This suggests that thyroid autoimmunity may act as an endophenotype for bipolar disorder, although results are conflicting, and different studies did not confirm these findings (Cobo *et al.* 2015). Moreover, offspring of subjects with bipolar disorder are more susceptible to thyroid autoimmunity. Hillegers *et al.* (2007) noticed a larger percentage of thyroid peroxidase antibody positivity in female bipolar offspring compared with healthy control subjects, and the majority of these thyroid peroxidase antibody-positive individuals also had raised levels of TSH. Susceptibility to autoimmunity seems to be independent of the child's risk of developing a psychiatric disorder, but further research is needed. The exact role of sex in thyroid autoimmunity in people with bipolar disorder is still unclear. Cobo *et al.* (2015) found that TSH and T_4 levels were not affected by sex, even if women had greater thyroglobulin antibody and thyroid peroxidase antibody positivization. Other authors found no significant correlation between sex and thyroid autoantibodies (Kupka *et al.* 2002).

HPG Axis

The HPG axis has been implicated in the development of bipolar and related disorders. Women with bipolar disorder have significantly higher rates of early-onset menstrual cycle dysfunction compared with women with unipolar depression and healthy control subjects (Joffe *et al.* 2006). In fact, menstrual dysfunction may precede the diagnosis of bipolar disorder, as suggested by Rasgon *et al.* (2000). This hypothesis was confirmed in 50% of the women in a larger study from the same group (Rasgon *et al.* 2005). Additionally, the study found that preexisting menstrual cycle abnormalities were associated with increased 17a-OH progesterone, LH/FSH ratio, and free testosterone, suggesting HPG axis dysfunction in these patients. However, most of these studies reported small sample and effect sizes, limiting the translational impact of these findings in a clinical setting. Menstrual cycle dysfunction in bipolar disorder has also been associated with changes in testosterone levels (O'Donovan *et al.* 2002; Rasgon *et al.* 2005).

Interestingly, testosterone levels were found to be positively correlated with the number of manic episodes and the number of suicide attempts in both males and females (Sher *et al.* 2012). This latter finding was further confirmed in a longitudinal study of the same group. In female patients with bipolar disorder, higher baseline testosterone levels predicted suicide attempts in a 2.5-year follow-up period (Sher *et al.* 2014). However, results are conflicting. Indeed, in the previously reported study by Feng *et al.* (2019), the authors found that first-episode patients with bipolar disorder showed reduced testosterone secretion.

Obviously, there is a substantial difference between male and female hormonal physiologies. Wooderson *et al.* (2015) reported that women with bipolar disorder had significantly higher testosterone levels compared with female control subjects, whereas men with bipolar disorder had lower testosterone levels compared with male control subjects. Thus, sex differences need to be considered in further research.

Hypothalamic-Neurohypophyseal System

Only very few studies have analyzed AVP in patients with bipolar disorder, mostly in depressive phases and in mixed samples of individuals with bipolar disorder or MDD, with no conclusive results (Rutigliano *et al.* 2016). Ozsoy *et al.* (2009) found significantly lower oxytocin levels in depressed patients (unipolar and bipolar) compared with healthy control subjects, but only in females. On the other hand, some studies on patients with bipolar disorder reported heightened oxytocin levels (Lien *et al.* 2017; Turan *et al.* 2013). In a recent postmortem study on patients with a major psychiatric disorder, the authors found that a diagnosis of MDD or bipolar disorder was associated with significantly increased oxytocin receptor mRNA levels in the dorsolateral prefrontal cortex (Lee *et al.* 2018). Remarkably, in subjects with either MDD or bipolar disorder, a specific SNP of the oxytocin receptor gene was associated with suicide attempt history (Parris *et al.* 2018).

Schizophrenia Spectrum and Other Psychotic Disorders

HPA Axis

HPA axis abnormalities have been demonstrated in individuals with psychosis and schizophrenia spectrum disorders. Recent meta-analyses have found evidence for elevated blood cortisol levels in individuals with first-episode psychosis (FEP), with larger effect sizes in studies investigating antipsychotic-naive participants (Borges *et al.* 2013; Hubbard and Miller 2019). Girshkin *et al.* (2014) analyzed morning cortisol levels in schizophrenia and found that participants free of antipsychotic medication similarly displayed significantly higher morning cortisol levels compared with control subjects, and higher morning cortisol levels were found in medication-free participants compared with those medicated. In addition, in individuals with FEP, antipsychotic medications can normalize the diurnal cortisol hypersecretion, but not the blunted CAR (Mondelli *et al.* 2010). These analyses provide evidence for HPA axis dysregulation in patients with psychotic disorders and suggest a dampening effect of antipsychotic medication on blood cortisol levels.

Thus, studying high-risk or medication-naive individuals is a valuable approach that may provide insight into HPA axis activity not confounded by medication. Prior studies investigating patients at high risk of developing psychosis found associations between those displaying prodromal and psychotic symptoms and increased cortisol levels (Corcoran *et al.* 2012; Mittal and Walker 2011). More recently, Cullen *et al.* (2020) found a direct connection between elevated cortisol levels and individuals who subsequently converted to psychosis, suggesting that HPA axis dysregulation begins before onset of disease. Additionally, pituitary volume enlargement has been shown to predict onset of psychosis in ultra-high-risk individuals (Garner *et al.* 2005) and has also been observed in FEP (Buschlen *et al.* 2011) and schizophrenia (Takahashi *et al.* 2018). Interestingly, one study found pituitary gland enlargement in unaffected relatives of patients with schizophrenia, suggesting a potential genetic association (Mondelli *et al.* 2008); however, more recent studies have not found such abnormalities (Cullen *et al.* 2015; Habets *et al.* 2012).

Recently, a meta-analysis investigated the concordance between naturally occurring psychosocial stressors and cortisol levels in individuals with established psychosis, high-risk subjects, and healthy control subjects (Cullen *et al.* 2020). There were no significant differences in cortisol response to psychosocial stressors between any of the groups, suggesting cortisol abnormalities in psychosis spectrum disorders are more likely due to the accumulation of global physiological dysregulation rather than to greater sensitivity to psychosocial stressors (Cullen *et al.* 2020). It should be noted that there was heterogeneity between studies and small numbers of participants; thus, further research is required.

As seen in depression and bipolar disorder, GR dysfunction is present in individuals with psychosis. Both first-episode unmedicated and chronic schizophrenia patients have decreased GR mRNA levels compared with control subjects (Liu *et al.* 2020; Sinclair *et al.* 2011), while patients with chronic schizophrenia have lower GR and neuron-specific enolase mRNA expression compared with those with first-episode schizophrenia (Liu *et al.* 2020). This difference suggests additional HPA axis dysregulation as schizophrenia progresses. However, it is difficult to identify the effect of treatments for psychosis in such a relationship. Furthermore, in a group of high-risk females with the same cortisol levels, increased GR expression was associated with increased conversion to psychosis (Iftimovici *et al.* 2020), indicating a role for genetic and epigenetic regulation. Thus, these studies provide a possible contributing cause for the HPA axis dysregulation discussed above.

In individuals with FEP, cortisol levels independently predict a smaller left hippocampal volume (Mondelli *et al.* 2011). In addition, patients with FEP who do not respond to treatments have markedly lower CAR at baseline, which persists after 12 weeks (Mondelli *et al.* 2015).

HPT Axis

Although the exact relationship between the HPT axis and psychotic disorders is unclear, multiple studies have found an association between abnormal thyroid hormone status and schizophrenia. Serum levels of total T_4 have been found to be elevated in acutely ill schizophrenia patients, with a positive correlation between T_4 levels, severity of illness, and degree of clinical response to antipsychotic treatment (Baumgartner *et al.* 2000). In a more recent study of 486 inpatients with schizophrenia, total T_3 and T_4 levels were significantly lower in both first-episode and recurrent schizophrenia patients compared with control subjects (Zhu *et al.* 2020); thus, the exact direction of HPT axis dysregulation is not clear. Nevertheless, free T_3 and T_4 are repeatedly elevated in FEP and acute schizophrenia (Jose *et al.* 2015; Zhu *et al.* 2020). There is also a correlation between free T_3 and T_4 levels and severity of disease, suggesting an association between thyroid hormone levels and severity of symptoms in schizophrenia (Jose *et al.* 2015; Sim *et al.* 2002).

When first-episode and recurrent schizophrenia are compared, first-episode individuals have significantly higher free T_3 and T_4 levels, and significantly lower TSH levels, than patients with recurrent schizophrenia (Zhu *et al.* 2020). Additionally, high rates of hypothyroidism have more frequently been reported in patients with schizophrenia spectrum disorders compared with those without (Hendrie *et al.* 2014; Radhakrishnan *et al.* 2013). These results indicate a change in HPT axis regulation with disease progression, possibly due to the addition of antipsychotic drug treatment.

HPG Axis

Gender and sex hormone differences in schizophrenia are widely reported and affect disease onset, symptoms, and disease progression (Gogos *et al.* 2019). For example, women manifest more positive and affective symptomatology compared with men (Goldstein and Link 1988) and have lower remission and relapse rates (Ochoa *et al.* 2012). Furthermore, throughout a woman's life, psychotic episodes are less common during pregnancy and the luteal phase of the menstrual cycle, when estrogen is increased (Bergemann *et al.* 2007), and more common during times of estrogen withdrawal, such as postpartum and during menopause (Kendell *et al.* 1987; Mahe and Dumaine 2001). There is a midlife increase in female diagnoses of schizophrenia correlating with menopause, with twice as many women as men being diagnosed after age 40 (Riecher-Rossler 2017). Therefore, this literature suggests that fluctuations in estrogen play a role in symptoms and onset of schizophrenia spectrum disorders.

Low serum estradiol and progesterone are reported in both men and women with schizophrenia (Belvederi Murri *et al.* 2016; Bergemann *et al.* 2007; Dogan Bulut *et al.* 2016), with a positive correlation between estradiol level, progesterone level, and score on the Scale for the Assessment of Negative Symptoms (SANS) in men (Dogan Bulut *et al.* 2016). However, in a study of first-episode antipsychotic-naive patients with schizophrenia, higher baseline levels of progesterone were seen in unmedicated than in medicated patients (Cai *et al.* 2018), suggesting that antipsychotic medication may impact HPG regulation. In this study, it was suggested that lower baseline levels of progesterone may be predictive of better therapeutic outcome following antipsychotic treatment.

A recent meta-analysis also found elevated dehydroepiandrosterone-sulphate (DHEA-S) and free testosterone in male and female patients with FEP, and elevated

total testosterone in acutely relapsed schizophrenia patients (Misiak *et al.* 2018). An inverse correlation has repeatedly been seen between testosterone levels and negative scores at the Positive and Negative Syndrome Scale (PANSS) in men, suggesting that testosterone plays a role in the severity of negative symptoms (Ko *et al.* 2007; Sisek-Sprem *et al.* 2014). These findings indicate HPG axis dysfunction in schizophrenia; however, the mechanisms underlying these hormonal changes are unclear and thus further investigation is required.

As discussed, concentrations of both estrogens and androgens during pregnancy may influence the development of mental changes in the postpartum period (Parizek *et al.* 2014). Notably, postpartum psychosis might mirror the acute changes in sex hormones that occur within the first hours and days after delivery, in contrast to postpartum depression, which usually occurs weeks later (Sawyer *et al.* 2019).

Hypothalamic-Neurohypophyseal System

Both oxytocin and AVP levels are altered in psychosis. In their study on male patients with nonacute schizophrenia, Jobst *et al.* (2014) found significantly lower plasma levels of both oxytocin and AVP in patients compared with control subjects. Results are not consistent throughout the literature. Rubin *et al.* (2014) observed significantly lower AVP levels in individuals with schizophrenia and their relatives compared with control subjects, but no differences in oxytocin levels. Postmortem studies revealed low AVP mRNA expression in hypothalamic PVN in individuals with schizophrenia compared with controls (Busch *et al.* 2019). Conversely, another study reported lower plasma oxytocin levels in schizophrenia subjects compared with control subjects, but no differences in AVP levels (Aydin *et al.* 2018). Also, SNPs of the oxytocin receptor have been associated with schizophrenia. Haram *et al.* (2016) found that rs237902 was associated with disorder-specific low amygdala activation, measured at the fMRI189. This same SNP was associated with negative symptoms of schizophrenia in a study by Montag *et al.* (2013), in which two other SNPs (rs53576 and rs237885) were found to be associated with a diagnosis of schizophrenia.

Trauma-and Stressor-Related Disorders

HPA Axis

HPA axis abnormalities are present in PTSD but vary across individuals and groups because of the frequent association with confounding factors (e.g., gender, developmental timing of trauma) and comorbid psychiatric disorders (especially depression). Therefore, PTSD's associations with neuroendocrine conditions are complicated and often not single-faceted (D'Elia *et al.* 2021). Studies of male combat veterans with PTSD demonstrated both enhanced cortisol suppression in response to dexamethasone and low cortisol levels (Wahbeh and Oken 2013; Yehuda 2002). However, participants differ in respect to comorbid diagnoses, with a large proportion having depression or depressive symptoms. Nevertheless, in a meta-analysis that excluded studies investigating PTSD with comorbid disorders, morning salivary cortisol levels were still found to be lower in patients with PTSD compared with controls (Pan *et al.* 2018). Female domestic violence or childhood abuse survivors with PTSD similarly show enhanced cortisol suppression in response to dexamethasone and low morning plasma cortisol levels, regardless of comorbid depression (Griffin *et al.* 2005; Stein *et al.* 1997),

thus providing evidence for enhanced negative feedback inhibition in PTSD, as opposed to what has been observed in depression (Yehuda 2002). Additionally, cerebrospinal fluid CRH concentrations have been found to be higher in patients with PTSD than in healthy controls, whereas ACTH response was blunted, suggesting a downregulation of CRH receptors within the anterior pituitary of these patients (Bremner *et al.* 1997). However, more recent research has found that women who developed PTSD after a sexual assault had higher cortisol levels at 10 P.M., greater CAR, and higher ACTH levels compared with control subjects, and ACTH levels increased with PTSD severity (D'Elia *et al.* 2021). Forty-six percent of these participants had comorbid depression; thus, an interaction between depression pathophysiology and HPA axis regulation may have been present. This comorbidity would explain the elevated ACTH and cortisol levels seen in depressed patients, in contrast to the decreased levels commonly seen in PTSD.

Yehuda *et al.* (2015) demonstrated decreased GR methylation in PTSD patients without comorbid depression compared with those with comorbid depression, providing a possible explanation for the differences in HPA axis response and GR sensitivity. Interestingly, differences in cortisol reactivity after recalling past traumatic events have been seen in PTSD patients with comorbid depression compared with those without. In a study of 60 survivors of the World Trade Center attacks, participants were asked to recall their escape from the attacks (Dekel *et al.* 2017). Following recollection, salivary cortisol levels were measured and were significantly decreased in the group with comorbid depression, were significantly increased in the PTSD-only group, and remained the same in the no-pathology group. These findings suggest that HPA axis pathophysiology in individuals with PTSD and comorbid symptoms differs from that in individuals with PTSD alone.

HPT Axis

Research on the relationship between HPT axis regulation and PTSD is limited; however, there is some evidence for an association between exposure to civilian trauma or combat and abnormal HPT axis activity. In World War II veterans, elevated serum total and free T_3 levels were observed (Wang and Mason 1999), and earlier research of combat veterans also found elevated levels of total T_3, free T_3, and total T_4 (Mason *et al.* 1994). Additionally, significantly lower TSH levels were found in 39 civilians with unmedicated PTSD compared with control participants when background variables were controlled (Olff *et al.* 2006). However, a recent meta-analysis involving 10 observational studies and 373 participants with PTSD reported higher levels of total and free T_3 in PTSD subjects compared with control subjects, whereas no differences were seen in TSH levels and total and free T_4 levels (Toloza *et al.* 2020).

HPG Axis

Epidemiological studies have repeatedly found that women develop PTSD around twice as frequently as men following exposure to trauma; thus, being female is one of the best-known risk factors for PTSD (Gogos *et al.* 2019). It has been hypothesized that these differences are mediated by changes in levels of gonadal hormones such as estrogen, which has a role in fear extinction (Maddox *et al.* 2018). For example, among women with PTSD, those who had low estradiol levels showed stronger intrusive memories following fear conditioning procedures (Wegerer *et al.* 2014) and increased PTSD symptoms in comparison with those who had high estradiol levels (Glover *et al.* 2012). Therefore, these studies suggest a possible role for estrogen in risk and severity of PTSD. However, clinical data are limited and are derived from small numbers of participants. More research into the association and mechanisms of HPG axis regulation in PTSD is needed.

Hypothalamic-Neurohypophyseal System

Evidence on hypothalamic-neurohypophyseal system alterations in trauma-related disorders is still scarce. Recent research suggests that oxytocin and AVP levels do not differ between individuals with PTSD and control subjects (Engel *et al.* 2019, 2021). However, some data suggest that people with PTSD may have lower oxytocin levels compared with healthy subjects (Carmassi *et al.* 2021).

Clinical Implications

The neuroendocrine system has a fundamental role in mental illnesses. Recognizing and acting on specific neuroendocrine components may open new paths for diagnosis, treatment, and prevention of psychiatric disorders. Notably, several psychiatric treatments act on the neuroendocrine system. On the other hand, different medications specifically targeting this system (at different levels) are currently under investigation for psychiatric disorders, and new ones may be developed in the upcoming years. Nevertheless, there are no conclusive results yet, and further research is required. In this section, we provide an overview of the different neuroendocrine systems and their potential implications for clinical psychiatry.

Hypothalamic-Pituitary-Adrenal Axis

The HPA axis has been increasingly studied as a potential target for treatment of different psychiatric disorders. The importance of this axis in psychiatric treatment is further confirmed by the fact that almost every psychotropic drug influences the HPA axis (Subramaniam *et al.* 2019). Antidepressants are mainly--but not always--associated with a reduction in cortisol levels, both basal and postdexamethasone/CRH suppression test, while psychostimulant medications are more frequently associated with an increase (or no changes) in basal cortisol levels (Subramaniam *et al.* 2019).

It is particularly important to highlight the clinical value of GR. Medications for depression require GR in order to exert their antidepressant action (Anacker *et al.* 2011). In fact, antidepressants activate GR in order to increase neurogenesis, while cortisol exerts the opposite effect (Pariante 2017). Binder *et al.* (2004) demonstrated, in a sample of depressed subjects, that specific *FKBP5* SNPs were linked with treatment response. Similar findings were reported by Ising *et al.* (2019). They demonstrated increased expression levels of *FKBP5* and its product, FKBP51, to be associated with nonresponse to antidepressant treatment in depressed individuals. In another recent systematic review (Fischer *et al.* 2019b), the authors demonstrated specific SNPs and haplotypes in genes related to CRH (*CRHBP*, *CRHR1*) and melanocortins (*POMC*) were predictive of nonresponse to antidepressants. They nonetheless reported inconclusive findings on GR- and MR-related genes. In the BIODEP study, the authors found that resistance to antidepressants was associated with lower expression of GR mRNA together with high expression of proinflammatory mRNAs (Cattaneo *et al.* 2020). These findings support the notion that the increased inflammation in depression is associated with glucocorticoid resistance, at least as indicated by the low expression of GR mRNA. Given this evidence, it is not surprising that adjunctive treatment with anti-inflammatory medications is a treatment strategy currently in clinical trials, with the aim of targeting inflammation in individuals with elevated levels of inflammatory biomarkers (Nettis *et al.* 2021). In addition, serotonergic transmission is crucial to both antidepressants and HPA axis functioning. Long-term treatment with antidepressants can indeed modulate serotonergic transmission by acting on serotonin receptors. The serotonergic modulation induced by SSRIs may lead to activation of the HPA axis, which in turn may unfavorably affect serotonin receptor functioning. This mechanism may be--at least partly--responsible for sensitization and/or tolerance to treatment (Fornaro *et al.* 2019).

Different antiglucocorticoid compounds have been studied in mood disorders, mainly as antidepressants (Cleare *et al.* 2015). In their review, Holsboer and Ising (2008) reported the results of two clinical studies on CRH receptor antagonists NBI-30775/R121919 and NBI-34041. Results were encouraging, since the first compound demonstrated a clinical profile that was comparable to the antidepressant paroxetine, and the second one reduced the stress-elicited secretion of cortisol. Mifepristone is a potent competitive GR antagonist and has been evaluated in the treatment of depression, both as augmentation and as monotherapy (Maric and Adzic 2013). Mifepristone has also been trialed in the treatment of bipolar depression, as an adjuvant to current treatment (mood stabilizers, antidepressants, and antipsychotics) (Young *et al.* 2004). A significant improvement in depression rating scores was seen in patients taking mifepristone compared with placebo. Furthermore, significant improvements in neurocognitive functioning were observed. Interestingly, mifepristone has also demonstrated effectiveness in reducing psychotic symptoms in depression with psychotic features (Block *et al.* 2018). On the other hand, Ferrier *et al.* (2015) found no beneficial effects on depressive symptoms for metyrapone--a competitive inhibitor of 11b-hydroxylase (with resulting inhibition of cortisol)--in patients with treatment-refractory depression. A recent meta-analysis by our research group in individuals with mood disorders (both depression and bipolar disorder) (Lombardo *et al.* 2019) showed that only subjects with higher baseline cortisol levels may benefit from treatment with cortisol synthesis inhibitors, supporting a potential role for cortisol as a predictive biomarker in people with mood disorders.

The neurosteroid allopregnanolone is an FDA-approved treatment for postpartum depression (Walton and Maguire 2019). Among its properties, it acts as a positive allosteric modulator at $GABA_A$ receptors, which may account for its anxiolytic and antidepressant effects. Also, allopregnanolone is involved in the stress response system and may regulate HPA axis activity by acting on hypothalamic neurons under protracted stressful conditions (Almeida *et al.* 2021). Therefore, it may be a promising target also for the treatment of trauma-and stressor-related disorders (such as PTSD), but further research is needed.

A recent systematic review highlighted the potential procognitive effects of the glucocorticoid precursor pregnenolone in individuals with schizophrenia (Soria *et al.* 2018). Another systematic review in the Cochrane Schizophrenia Group's Trials Register analyzed data from 11 studies that randomly assigned treatment conditions to

509 people with schizophrenia, schizoaffective disorder, or psychotic depression, comparing antiglucocorticoids and related drugs with placebo (Garner *et al.* 2016). Even though further research is needed, preliminary evidence suggests a beneficial effect for mifepristone (with few overall adverse effects) compared with placebo (Garner *et al.* 2016).

Another recent systematic review and meta-analysis involving 362 participants from eight randomized controlled trials (RCTs) demonstrated that administration of hydrocortisone could be effective in the prevention of PTSD symptoms, but not in their treatment (Kothgassner *et al.* 2021).

Finally, an important role is played by the gut microbiota, which is profoundly linked to the HPA axis. The gut microbiota includes all the indigenous microorganisms that live in the human gut. This assemblage of microorganisms has an important role in mediating the response to stress (Baumgartner *et al.* 2000; Farzi *et al.* 2018; Sudo 2014). Perturbations in gut microbiota composition have been transdiagnostically associated with different psychiatric conditions, including depression, bipolar disorders, and schizophrenia (Nikolova *et al.* 2021). Moreover, the gut microbiota seems to be involved in treatment resistance in both depression (Fontana *et al.* 2020) and schizophrenia (Manchia *et al.* 2021). Notably, probiotics are now emerging as a new potential adjunctive treatment for different psychiatric diseases, such as depression (Butler *et al.* 2019; Vlainic Vlainic *et al.* 2016).

Hypothalamic-Pituitary-Thyroid Axis

Different psychotropic medications may affect the HPT axis as well. Lithium is one of the most effective treatments for bipolar disorder, and hypothyroidism--with a reduction of circulating levels of thyroid hormones--is one of the most common side effects of long-term lithium use. Nevertheless, several studies reported that the increased presence of thyroid peroxidase antibodies in patients with bipolar disorder compared with control subjects was not associated with lithium exposure (Barbuti *et al.* 2017; Kupka *et al.* 2002). Also, other psychotropic medications may affect thyroid function. In their recent study on patients with bipolar disorder, Li *et al.* (2019) found no differences in thyroid profiles in patients with different mood episodes; they did find, however, that treatment with quetiapine could affect thyroid function, significantly reducing levels of thyroid hormones. Following antipsychotic drug treatment, free T_3 and T_4, total T_4, and reverse T_3 levels decrease or normalize, while TSH levels increase, thus suggesting an interaction between thyroid hormone metabolism and antipsychotic medication (Baumgartner *et al.* 2000; Bunevicius *et al.* 2014; Santos *et al.* 2012). The decrease in total T_4 following an antipsychotic medication regimen is correlated with clinical response, indicating that normalization or reduction of HPT axis hormones can be a parameter for measuring recovery (Baumgartner *et al.* 2000; Santos *et al.* 2012).

Most of the evidence on the HPT axis and treatment of psychiatric diseases comes from studies of mood disorders, especially depression. Even though it is obvious that thyroid hormone supplementation is beneficial in hypothyroidism, there is evidence that it may also improve depressive symptoms in patients with a normal thyroid function. Notably, augmentation with T_3 has demonstrated efficacy in treatment-resistant depression (Carvalho *et al.* 2009). In addition, T_4 may have neuroprotective effects by acting on BDNF, with a mechanism similar to antidepressants (Hung *et al.* 2013). Interestingly, Baek *et al.* (2014) found an association between higher TSH levels and lower baseline and reduced increase in BDNF levels during antidepressant treatment. Thus, they suggest the HPT axis may be crucial in mediating the antidepressant response.

Even though only very few studies have examined the use of T_3 in bipolar depression, findings are encouraging (Parmentier and Sienaert 2018). Clinical trials involving patients with rapid-cycling bipolar disorder demonstrated that treatment with levothyroxine was associated with significantly less time in a depressed or mixed state, and more time in a euthymic state, compared with placebo (Walshaw *et al.* 2018). In addition, both subclinical hypothyroidism and higher TSH levels still within the normal range (> 2.5 mIU/mL) have been associated with poorer antidepressant response in unipolar and bipolar depression (Cohen *et al.* 2018). Thus, the optimization of TSH levels with thyroid hormone supplementation may be an effective treatment strategy in depressed patients with high-normal TSH levels and poor antidepressant response (Cohen *et al.* 2018).

Hypothalamic-Pituitary-Gonadal Axis

Several psychotropic medications may affect the HPG axis--mainly antipsychotics and antidepressants, but also mood stabilizers (Drobnis and Nangia 2017). In fact, both first-and second-generation antipsychotics can antagonize dopamine receptors (mainly D_2), increasing the levels of prolactin and decreasing the release of gonadotropin. Hyperprolactinemia may be a clinical issue both in women and in men. It usually manifests with infertility and sexual dysfunctions. Chronically, it may lead to osteolysis. There are, however, important differences between different molecules. For example, with certain second-generation compounds, such as aripiprazole and cariprazine, which are partial agonists of dopamine receptors, these effects are markedly reduced. Also, several antidepressants with serotonergic activity, including SSRIs, monoamine oxidase inhibitors (MAOIs), and some tricyclics, may increase prolactin levels by acting on dopamine signaling (inhibition of the reuptake) (Torre and Falorni 2007). Lithium also has been demonstrated to increase prolactin and LH and to decrease sex hormones levels. Lastly, anticonvulsants may decrease free or bioavailable testosterone, with variable effects on the other reproductive hormones (Drobnis and Nangia 2017). In particular, valproate has been associated with high rates of menstrual abnormalities, hyperandrogenism, and polycystic ovary syndrome (O'Donovan *et al.* 2002).

Even though sex is always a variable to account for, there is some evidence pointing to the role of both testosterone and estrogens in mental well-being, independent of sex. McHenry *et al.* (2014) discussed in their review the antidepressant effects of testosterone in both women and men. A proposed mechanism to explain this potential effect is the activation of the hippocampal mitogen-activated protein kinase (MAPK) pathway. Therefore, supplementation with testosterone (intramuscular, transdermal, or oral) has been evaluated as an adjunctive treatment for depressed men, especially for partial responders with low or borderline testosterone levels (Kanayama *et al.* 2007). Pope *et al.* (2003) reported that testosterone transdermal gel was effective in reducing depressive symptoms in male subjects with refractory depression and low or borderline testosterone levels. However, these findings were not replicated in a subsequent larger study of the same group, in which testosterone supplementation failed to significantly reduce depressive symptoms compared with placebo (Pope *et al.* 2010). Despite conflicting findings, a recent meta-analysis of 27 placebo-controlled RCTs confirmed the efficacy and effectiveness of testosterone in reducing depressive symptoms in men, particularly at a high dosage (Walther *et al.* 2019). Treatment with testosterone is relatively safe, especially if testosterone levels are kept in the normal range. However, long-term effects on major cardiovascular events and prostate cancer risk are still uncertain (dos Santos and Bhasin 2021). Also, low-dose transdermal testosterone was found to improve depressive symptoms in women with treatment-resistant depression (Miller *et al.* 2009). This antidepressant effect with low doses of testosterone may be due to a greater sensitivity to androgens in women compared with men. In their study of treatment-resistant depression in women, Huang *et al.* (2008) reported that menopausal status and ovarian steroid levels (but not age) were the main determinants of antidepressant efficacy of repetitive transcranial magnetic stimulation, both in MDD and in bipolar disorder. Notably, perimenopausal depression may be directly associated with the fall in ovarian estrogen production (estradiol withdrawal). Therefore, hormone replacement therapy (with estradiol) may be a promising strategy to treat or prevent the development of depression in susceptible women (Schmidt and Rubinow 2009; Schmidt *et al.* 2015).

There is ongoing research on the use of adjunctive hormone therapies for treatment of schizophrenia. Administering 17b-estradiol or ethinyl estradiol alongside stable antipsychotic use has been shown to significantly decrease PANSS positive, general, and total symptoms in female schizophrenia or schizoaffective disorder patients compared with placebo groups (Akhondzadeh *et al.* 2003; Kulkarni *et al.* 2015). Furthermore, in a cross-sectional study of postmenopausal women with schizophrenia, users of hormone replacement therapy received lower average daily doses of antipsychotic medication and had less severe negative symptoms compared with non-users of hormone replacement therapy (Lindamer *et al.* 2001). However, despite these positive results, estradiol (especially at an efficacious dose) may have serious health risks, such as thromboembolism and endometrial hyperplasia (Gogos *et al.* 2015). Therefore, further research is required on the underlying mechanisms of protective effects of estrogens, along with the potential for estrogen treatment in men. In women with schizophrenia, menstrual cycle irregularity was associated with poorer cognitive performance (Gurvich *et al.* 2018). Notably, the selective estrogen receptor modulator raloxifene has demonstrated beneficial effects on cognition in schizophrenia (Soria *et al.* 2018).

We already discussed how the interconnection between the HPG and the HPA axes may be critical in the relationship between HPG and psychiatric disorders. In this regard, Mou *et al.* (2017) demonstrated antidepressant properties of the ginsenoside Rg1 in mice. Rg1 is an active compound of the plant genus *Panax* (ginseng) that exerts several biological functions, including sex hormone-like activities and GR modulation. Notably, mice treated with Rg1 presented significantly lessened depressive-like symptoms, together with reduced glucocorticoid levels and increased testosterone levels, in comparison with untreated mice.

Hypothalamic-Neurohypophyseal System

Given the evidence we discussed on the neurohypophyseal system and its connections with other neuroendocrine and immune pathways, it is not surprising that AVP and oxytocin have been studied for their therapeutic potential in psychiatric disorders.

Antagonism of the AVP receptor AVPR1b has been demonstrated to have antidepressant effects (Neumann and Landgraf 2012). Nevertheless, Griebel *et al.* (2012) found no conclusive evidence from three randomized double-blind, placebo-controlled studies involving depressed individuals taking an AVPR1b antagonist (SSR149415) for 8 weeks. Notably, several psychotropic medication classes, such as antidepressants (mainly SSRIs, but also tricyclics, MAOIs, and venlafaxine) and anticonvulsants (such as valproic acid, carbamazepine, and oxcarbazepine), may affect AVP levels and cause SIADH (Liamis *et al.* 2008; Spasovski *et al.* 2014). The precise mechanisms of this biological effect have yet to be clarified. However, the increase in AVP secretion may be caused by the effects on serotonin and norepinephrine transmission (De Picker *et al.* 2014) or by a direct effect on renal sensitivity to AVP (Sachdeo *et al.* 2002).

There is preclinical and clinical evidence that oxytocin, both peripherally and centrally administered, may counteract depression (Matsuzaki *et al.* 2012; Neumann and Landgraf 2012). In addition, these antidepressant effects remain even after the administration of an oxytocin receptor antagonist (Acevedo-Rodriguez *et al.* 2015). This evidence suggests that the antidepressant effects are differently mediated, perhaps as a result of the crosstalk with AVP receptors (Manning *et al.* 2012). Also, oxytocin can increase dopamine transmission, through D_1 receptor activation, in the medial prefrontal cortex, thus exerting antidepressant effects (Li *et al.* 2020). There is still active debate on the effectiveness of oxytocin administration to prevent postpartum depression. Some evidence suggests that oxytocin may negatively affect maternal mood (Kroll-Desrosiers *et al.* 2017; Mah 2016). However, other findings demonstrate that it can protect against future development of postpartum depression, even without immediate effects on maternal mood (Takacs *et al.* 2019).

Different studies analyzed the efficacy of oxytocin administration in ameliorating psychotic symptoms. Feifel *et al.* (2010) administered intranasal oxytocin (titrated to 40 IU twice a day) to 15 subjects with residual symptoms of schizophrenia for 3 weeks. Oxytocin significantly reduced scores on the PANSS and the Clinical Global Impression (CGI) Scale compared with placebo (Feifel *et al.* 2010). Another trial with a lower dosage (24 IU twice a day) and duration (2 weeks) confirmed a significant effect of intranasal oxytocin on PANSS scores (Pedersen *et al.* 2011). A recent meta-analysis of nine RCTs found that higher doses of intranasal oxytocin may be effective in improving negative symptoms of schizophrenia, with a moderate effect size (Sabe *et al.* 2021). However, this effect disappeared after the exclusion of one outlier, and thus no firm conclusions about this association could be drawn (Sabe *et al.* 2021).

Moreover, oxytocin administration may help to ameliorate the neurocircuitry connectivity dysfunction observed in individuals with PTSD (Crum *et al.* 2021). These findings were only partially confirmed in a recent study demonstrating that intranasal oxytocin (24 IU) modulates threat-related functional connectivity in individuals who were exposed to trauma in childhood (Sippel *et al.* 2021). However, this effect was not mediated by a diagnosis of PTSD and varied as a function of gender and hemisphere.

Conclusion

Mental health is a fundamental element of the whole individual's well-being, and psychiatric disorders are deeply interconnected with biological modifications in our bodies. With its unique focus on mind and body interactions, psychoneuroendocrinology may offer diverse perspectives for approaching mental health. Even though current evidence is still largely exploratory, research in this field may help to identify the biological mechanisms that are causes and/or consequences of psychiatric illnesses. Identifying these mechanisms may ultimately lead to a better characterization of psychiatric diagnoses and treatments.

CHAPTER 5

Brain-Immune System Interactions

Firdaus S. Dhabhar, Ph.D.
Charles L. Raison, M.D.
Andrew H. Miller, M.D.

Multidirectional interactions among psychological factors and the nervous, endocrine, and immune systems form the basis of important physiological pathways that are crucial for maintaining mental and physical health. These multisystem interactions can also mediate the pathological aspects of numerous diseases. Therefore, elucidating brain-immune system pathways and mechanisms is likely to be critically useful for restoring health in the presence of disease or promoting health in the absence of disease. In this chapter we begin with an overview of the immune system and introduce its three major functional dimensions. We then go on to describe the effects of stress and depression on immune function, the association between other psychiatric disorders and the immune system, and the pathways that mediate these effects and associations. The penultimate section covers the pathways that mediate the effects of the immune system on the nervous system and on mental and psychological states. Finally, we discuss the relevance of brain-immune interactions in the context of mental illness and its treatment.

The Immune Triad: Immunoprotection, Immunopathology, and Immunoregulation

The immune system is a highly distributed physiological system. It consists of primary (bone marrow and thymus), secondary (lymph nodes, spleen, tonsils, and parts of mucosal tissues), and tertiary (most other organs in the body) organs; immune cells or leukocytes (granulocytes, monocytes, T cells, B cells, natural killer cells); and humoral factors (e.g., antibodies, cytokines, complement peptides) that traverse the body through a network of vascular and lymphatic vessels. When we are discussing immune responses, it is useful to categorize them in terms of their principal cellular and molecular components. For example, innate, adaptive, and helper T cell (e.g., Th1, Th2, Th17) immune responses are all defined in terms of their cellular, cytokine, and humoral components. In addition to these categories, it is also useful to define immune responses in terms of their integrated functional effects. Dhabhar (2009a, 2009b, 2014, 2018) proposed that immune responses be categorized as being immunoprotective, immunopathological, and immunoregulatory/inhibitory. It is important to bear in mind that although such categories provide useful constructs with which to organize ideas, concepts, and models, an overall in vivo immune response is likely to consist of several types of responses with varying amounts of dominance from each category. The composition and nature of an immune response is also affected by--and changes with--time. The three major types of immune responses are defined below in terms of their functional end effects (Dhabhar 2009a, 2009b, 2014, 2018).

Immunoprotective responses are defined as those that promote efficient wound healing, eliminate infections and cancer, and mediate vaccine-induced immunological memory (Dhabhar 2009a, 2009b, 2018). Key characteristics of immunoprotection include active immune surveillance, a rapid and robust response on immune activation, and efficient clearance of the activating agent or pathogen, followed by rapid resolution. Immunoprotective responses are critical for completion of the proliferative and remodeling phases of wound healing. Wound healing is important not only for frank wounds (where the initiating event is tissue damage itself) but also for tissue-intrinsic "wounds" (where the initiating event is an immune response precipitated by intracellular infection, during which there can be collateral tissue damage). Different types and combinations of immune responses--innate, adaptive, Th1, Th2--can confer immunoprotection, depending on the type of pathogen involved (viral, bacterial, protozoan, fungal, helminthic), on whether the pathogen is intracellular or extracellular, and on the accompanying wounding conditions (sterile, infected, external, or internal wounds).

Immunopathological responses are defined as those that are directed against the self (as in autoimmune diseases such as multiple sclerosis, arthritis, or systemic lupus erythematosus) or against innocuous antigens (asthma, allergies) and responses that are directed against chronic, nonresolving inflammation (Dhabhar 2009a, 2009b, 2018). Immunopathology is also involved in low-level, long-term elevations in local and/or systemic inflammatory mediators (e.g., C-reactive protein [CRP] or interleukin 6 [IL-6]), which are thought to contribute to disorders such as cardiovascular disease, obesity, and depression (Dantzer *et al.* 2008; Maes 1993; Van Gaal *et al.* 2006).

Immunoregulatory responses are defined as those that involve immune cells and factors that regulate (mainly downregulate) the function of other immune cells (Dhabhar 2009a, 2009b, 2018). Although the earlier concept of suppressor T cells became mired in controversy, newer studies suggest that there is an arm of the immune system that functions to inhibit immune responses (Piccirillo 2008; Simpson 2008; Wing and Sakaguchi 2010). For example, $CD4^{+}CD25^{+}Foxp3^{+}$ regulatory T cells, IL-10, and transforming growth factor b have been shown to have immunoregulatory/inhibitory functions. The physiological function of these factors is to keep proinflammatory, allergic, and autoimmune responses in check (Bluestone and Tang 2005; Wing and Sakaguchi 2010). However, it

has also been suggested that immunoregulatory/inhibitory factors may suppress anti-tumor immunity and that their presence may be indicative of a negative prognosis for cancer (Finn 2008; Olson and McNeel 2013; Saul *et al.* 2005; Whiteside 2014).

Effects of the Brain and Behavior on the Body

More than four decades ago, Ader and Cohen (1975) showed that an immune response could be modified through classical Pavlovian conditioning. Numerous studies have confirmed and extended this initial insight and have established beyond argument the ability of brain states to significantly modulate immune system functioning (Bower and Irwin 2016; Irwin and Rothermundt 2012; Kelley and McCusker 2014; Nemeroff 2013; Padro and Sanders 2014; Quan 2014; Schedlowski *et al.* 2014; Straub 2014). The majority of these studies have focused on the effects of stress on the immune response (Dhabhar 2014, 2018; Straub *et al.* 2013).

Effects of Stress on Immune Function

Even though the word *stress* generally has negative connotations, stress is a familiar and ubiquitous aspect of life, representing a stimulant for some individuals but a burden for many others. Numerous definitions have been proposed for the concept of stress, each focusing on aspects of an internal or external challenge, disturbance, or stimulus; on stimulus perception; or on a physiological response (Goldstein and McEwen 2002; McEwen 2002; Sapolsky 2005). An integrated definition states that stress is a constellation of events consisting of a stimulus *(stressor)* that precipitates a reaction in the brain *(stress perception and evaluation)* that activates physiological fight-or-flight systems in the body *(biological stress response)* (Dhabhar and McEwen 1997).

Short-term stress involves changes in stress-related factors that last for minutes to hours, whereas chronic stress involves changes that last for months or years. The only way that a stressor can affect the brain or body is through the biological stress response. Although many factors are involved, the major mediators of stress effects are norepinephrine and epinephrine, which are released by the sympathetic nervous system, and corticotropin-releasing hormone (CRH), adrenocorticotropin, and cortisol, which arise following activation of the hypothalamic-pituitary-adrenal (HPA) axis. Virtually every cell in the body expresses receptors for one or more of these factors. Therefore, stress hormones can induce changes in almost all cells and tissues and inform them about the presence of a stressor. Virtually every type of stressor, ranging from laboratory stressors (e.g., public speaking, mental arithmetic) to life-related stressors (e.g., exercise, process of undergoing surgery, skydiving, bereavement, loneliness, academic examinations), has demonstrated a measurable effect on the immune system (Dhabhar 2014, 2018; Raison *et al.* 2002).

Although stress has a bad reputation, it is important to recognize that the adaptive purpose of a physiological stress response is to promote survival during fight or flight. Whereas long-term stress is generally harmful, short-term stress can be protective in that it prepares the organism to deal with threats or challenges. It has been proposed that a psychophysiological stress response is one of nature's fundamental survival mechanisms that could be therapeutically harnessed to augment immune function during vaccination, wound healing, or infection (Dhabhar 2009a, 2009b, 2014, 2018; Dhabhar and McEwen 1999; Dhabhar and Viswanathan 2005). Mechanisms of acute stress-induced immunoenhancement include the following:

1. Subpopulation-specific changes in neutrophil, macrophage, and lymphocyte redistribution (Dhabhar and McEwen 1997; Dhabhar *et al.* 2012; Rosenberger *et al.* 2009)
2. Increased leukocyte infiltration into sites of immune activation (Viswanathan and Dhabhar 2005)
3. Increased dendritic cell and macrophage maturation and traffic to draining lymph nodes (Viswanathan and Dhabhar 2005)
4. Enhanced local cytokine production, with a key role for interferon-g (IFN-g) (Dhabhar *et al.* 2000)
5. Enhanced systemic production of cytokines such as IL-1 and IL-6, which is also likely to contribute to enhancement of immune function

induced by short-term stress (Aschbacher *et al.* 2012; Puterman *et al.* 2014; Steptoe *et al.* 2001)

The adjuvant-like immunoenhancing effects of short-term stress may have evolved because many stressful situations (e.g., aggression, accident) result in immune activation (e.g., wounding, infection) and vice versa (Dhabhar 2014; Puterman *et al.* 2014). Interestingly, in modern times, many medical procedures involving immune activation (e.g., vaccination, surgery) also induce a stress response. Preclinical findings in animals initially lent support to this hypothesis (Dhabhar and McEwen 1996; Dhabhar *et al.* 1995; Viswanathan and Dhabhar 2005) and subsequently were replicated in humans. Clinical studies have demonstrated that patients undergoing knee surgery who show a robust and adaptive immune cell redistribution profile during the short-term stress of surgery also show significantly enhanced recovery (Rosenberger *et al.* 2009). Similarly, preclinical studies initially demonstrated that short-term stress that was experienced during primary (Blecha *et al.* 1982; Coe *et al.* 1989; Dhabhar and Viswanathan 2005; Viswanathan *et al.* 2005; Wood *et al.* 1993) or secondary (Blecha *et al.* 1982; Dhabhar and McEwen 1996, 1999; Dhabhar *et al.* 2000; Saint-Mezard *et al.* 2003) antigen exposure significantly enhanced the ensuing immune response (Dhabhar 2002). An elegant series of clinical studies has demonstrated that the adjuvant effects of short-term psychological stress, or exercise stress, can enhance vaccine-induced immunity in human subjects (Edwards *et al.* 2006, 2007, 2008).

We have defined chronic stress as that which results in stress-related biological changes that last for weeks, months, or years (Dhabhar and McEwen 1997). Figure 5-1 illustrates the steps and factors that mediate the transition from adaptive short-term stress to deleterious chronic stress.

FIGURE 5-1. Steps and factors that mediate the transition from adaptive short-term stress to deleterious chronic stress.

Time is represented on the x-axis, and changes in stress-related biological factors are represented on the y-axis. The *upright triangle* (**top panel**) represents an adaptive short-term stress response, where stress-related biological changes occur rapidly (within minutes) and resolve back to baseline rapidly (within minutes to hours). Life involves a series of stress "hits" and responses. Most humans and other organisms are built to handle this series of stress responses and can continue to mount adaptive/protective responses under such conditions, especially if their psychological and physiological systems return to baseline/resting conditions (*bars between triangles*) between stress hits. The *trapezoid* (**middle panel**) represents a prolonged short-term stress response with delayed shutdown that results in greater overall AUC (area under the curve) exposure to stress-related factors compared with the prototypical adaptive stress response. Such prolonged stress responses can begin to have deleterious effects, especially if they are part of a series of stress hits with little or no time of return to baseline/resting conditions between hits. The *long trapezoid* (**bottom panel**) is a graphical representation of chronic stress, which is known to have numerous deleterious effects on brain, body, and health and on mental and physical performance.

In contrast to short-term stress, chronic or long-term stress can be harmful (Dhabhar and McEwen 1997). Chronic stress suppresses or dysregulates innate and adaptive immune responses by altering the type 1-type 2 cytokine balance, inducing low-grade chronic inflammation and suppressing the numbers, trafficking, and function of immunoprotective cells (Dhabhar 2009a, 2009b, 2014). Chronic stress has been shown to increase susceptibility to infections, reduce antibody responses to vaccination, and delay wound healing (Cohen *et al.* 1991; Fagundes *et al.* 2013; Glaser and Kiecolt-Glaser 2005; Irwin 2008; Kiecolt-Glaser *et al.* 1995; Padro and Sanders 2014; Sanders and Straub 2002; Solomon 1969; Straub *et al.* 2013; Vitlic *et al.* 2014; Webster Marketon and Glaser 2008). Chronic stress also has been linked to increased morbidity and mortality in neoplastic diseases (including breast cancer and malignant melanoma), diabetes, and cardiovascular disease (Antoni *et al.* 2006; Ben-Eliyahu 2020; Ben-Eliyahu *et al.* 2007; Dhabhar 2014; Eckerling *et al.* 2021; Evans *et al.* 2005; Fenton and Stover 2006; Leserman *et al.* 1999; Lutgendorf and Sood 2011; Raison and Miller 2003; Saul *et al.* 2005). In addition to significant personal and health-related costs of chronic stress, the annual economic cost to industry arising from work-related stress in the United States is estimated at more than $300 billion (American Psychological Association 2007). Dysregulation of the circadian cortisol rhythm is an important marker that coincides with the deleterious effects of chronic stress (Dhabhar 2014; Dhabhar and McEwen 1997; Saul *et al.* 2005; Sephton and Spiegel 2003).

Key factors that determine whether stress enhances or suppresses immune function include the following (for reviews, see Dhabhar 2009a, 2009b, 2014, 2018):

1. The effects of stress on immune cell distribution in the body
2. The duration (short [minutes to hours] vs. long [weeks to months to years]) of changes in stress-related factors
3. The differential effects of physiological versus pharmacological concentrations of stress hormones and the differential effects of endogenous (e.g., cortisol, corticosterone) versus synthetic (e.g., dexamethasone) hormones
4. The timing of stressor or stress hormone exposure relative to the time of activation and ensuing time course of the immune response

It is important to recognize that factors such as gender, genetics, age, route of administration, nature of the immunizing antigen, and time during the circadian cycle additionally affect immune function and could also affect the nature of the relationship between stress and immune function. It is also important to bear in mind that it is not the effect of a particular stressor in enhancing or suppressing immune function but rather the end effect on the immune response that determines whether stress-immune system interactions have beneficial or harmful effects on health.

Effects of Depression on Immune Function

Numerous studies have investigated the effects of stress-related disorders, especially major depressive disorder (MDD), on immune function (Antonioli *et al.* 2012; Blume *et al.* 2011; Irwin and Miller 2007; Miller and Raison 2016). Despite a significant degree of heterogeneity across individual studies, evidence suggests that patients with MDD demonstrate a number of immune changes similar to those seen in individuals undergoing chronic and/or severe stress (Herbert and Cohen 1993; Zorrilla *et al.* 2001). This finding is hardly surprising, given the many indices of stress system hyperactivity that are apparent in patients with MDD, including increased CRH and cortisol production (Pariante *et al.* 1995) and augmented sympathetic nervous system activity as manifested in part by increased peripheral blood catecholamines (Veith *et al.* 1994; Wong *et al.* 2000). Enumerative immune changes shared by MDD and chronic or severe stress include decreases in lymphocytes, B cells, and T cells and increases in the ratio of CD4 to CD8 T cell subsets (Herbert and Cohen 1993). Shared functional changes include decreases in natural killer (NK) cell activity and lymphocyte proliferation in response to nonspecific mitogens (Table 5-1) (Herbert and Cohen 1993; Zorrilla *et al.* 2001). It is important to note, however, that MDD is a heterogeneous condition, and immune changes are not uniform across all patients. Indeed, inhibited lymphocyte responses tend to be most striking in patients who are older, are hospitalized, or have more severe and/or melancholic types of depression (Miller 1998; Schleifer *et al.* 1989). In addition, the sleep changes common in depression are known to alter lymphocyte responses, especially NK cell activity, even in the absence of other depressive symptoms (Irwin 2015; Irwin *et al.* 1996). Nonetheless, it does not appear that these factors completely account for the association between MDD and alterations in measures of the number and function of lymphocyte subsets (Herbert and Cohen 1993; Irwin and Miller 2007).

TABLE 5-1. Immune alterations in major depressive disorder

Increased white blood cells
Increased neutrophil percentage
Decreased lymphocyte percentage
Increased CD4-to-CD8 ratio
Decreased natural killer cell activity
Decreased mitogen-induced lymphocyte proliferation
Increased circulating interleukin 6
Decreased circulating interleukin 10
Increased haptoglobin
Increased prostaglandin E_2

Evidence suggests that depression, like chronic stress, may impair T cell function in ways that are relevant to disease vulnerability. For example, one study reported that patients with MDD have a marked decrease in the ability to generate lymphocytes that respond to the herpes zoster virus (Irwin *et al.* 1998). Also consistent with impaired T cell function in depression is the observation that depressed patients, especially those with melancholia, demonstrate impaired cell-mediated immunity (CMI), as measured by the delayed-type hypersensitivity response (Hickie *et al.* 1993, 1995). A recent study suggested that a potential interaction between MDD and sex might contribute to susceptibility to cytomegalovirus (CMV); women with MDD were more likely, and men with MDD were less likely, to be CMV positive (Ford *et al.* 2020). Relative to these findings, increasing interest has been generated by evidence that the deleterious effects of chronic CMV infection on white matter integrity may contribute to MDD (Zheng *et al.* 2021).

A growing database also indicates that depression in both medically healthy and medically ill patients is associated with increased immunopathological inflammatory responses (Andrei *et al.* 2007; Kim *et al.* 2007; Lesperance *et al.* 2004; Maes 1999; Miller and Raison 2016; Musselman *et al.* 2001). Findings consistent with inflammatory activation in depression include increased plasma and cerebrospinal fluid (CSF) concentrations of inflammatory cytokines, increased in vitro production of inflammatory cytokines from stimulated peripheral blood mononuclear cells, increased positive acute-phase proteins (and decreased negative acute-phase proteins), increased chemokines and adhesion molecules, and increased production of prostaglandins and reactive oxygen and nitrogen species (Kim *et al.* 2007; Maes 1999; Miller and Raison 2016; Raison *et al.* 2006).

On the basis of meta-analyses, increases in peripheral blood IL-6, tumor necrosis factor (TNF), and CRP are some of the most reliable inflammatory biomarkers associated with depression (Dowlati *et al.* 2010; Howren *et al.* 2009). Of interest, given the role of IL-6 and CRP in predicting disease outcome in both cardiovascular disorders and diabetes (Ridker *et al.* 2000a, 2000b), as well as data indicating that inflammation may play a role in cancer (Aggarwal *et al.* 2006), the relationship between depression and activation of the inflammatory response may provide a mechanism that explains the negative impact of depression on a number of illnesses (Evans *et al.* 2005). Moreover, immune activation in MDD may be involved in several of the pathophysiological changes that are common in the context of depression, including bone loss, increased body temperature, hippocampal volume loss, insulin resistance, hyperlipidemia, and the metabolic syndrome (Miller and Raison 2016; Miller *et al.* 2009).

It is important to recognize that in the absence of chronic infection, cancer, or immunodeficiency disease, modest elevations in antiinflammatory cytokines may exert salubrious or health-protective effects by mediating the resolution of inflammatory processes and preventing or antagonizing the damaging effects of prolonged inflammation. Therefore, it is also important to investigate the role played by antiinflammatory/immunomodulatory cytokines such as IL-10 in depression (Dhabhar *et al.* 2009). In healthy individuals, there is a regulated balance between pro-and antiinflammatory cytokines; for example, IL-6 mediates the early phase of the inflammatory process and induces the release of IL-10, which exerts immunoregulatory effects and resolves inflammation (Daftarian *et al.* 1996; Fang *et al.* 2008; Ogawa *et al.* 2008). The net result of such regulatory relationships is that the immune system can quickly respond to a challenge and subsequently return to homeostasis once the challenge has ended. Short-term inflammatory reactions in response to immune challenges such as wounding or infection are adaptive and essential for survival, but chronic inflammation is harmful. Interestingly, depression is associated with numerous disorders that are thought to involve chronic inflammation (Dantzer *et al.* 2008; Evans *et al.* 2005; Kiecolt-Glaser and Glaser 2002). These include cardiovascular disease (Frasure-Smith *et al.* 2007; McCaffery *et al.* 2006; Musselman and Nemeroff 2000; Whooley *et al.* 2007), obesity (Onyike *et al.* 2003), rheumatoid arthritis (Bruce 2008; Zautra *et al.* 2004), multiple sclerosis (Triantafyllou *et al.* 2008), and cancer (Currier and Nemeroff 2014).

A number of potential factors may contribute to increased inflammatory responses in depressed patients. One factor that has received special attention is BMI. BMI has been reliably correlated with peripheral markers of inflammation, including IL-6, in part related to the capacity of adipocytes to produce inflammatory cytokines (Schaffler *et al.* 2007). Early-life stress is another factor that may be involved. A meta-analysis by LeMoult *et al.*

(2020) suggests that early-life stress increases MDD risk early in development. Multiple studies have linked early-life stress with increased inflammation (Danese and Lewis 2017). For example, males with current MDD and a history of high early-life stress exhibited significantly greater increases in IL-6 and nuclear factor (NF)-kB DNA binding following a psychosocial stressor compared with nondepressed male control subjects (Pace *et al.* 2006).

It has been suggested that an important and relatively underappreciated mechanism for the link between depression and inflammatory disorders may be disruption of the immunoregulatory balance between pro-and antiinflammatory cytokines (Dhabhar *et al.* 2009). The cytokine balance can be tilted toward a proinflammatory milieu because of elevated concentrations of inflammatory cytokines such as IL-6, lowered concentrations of antiinflammatory/immunomodulatory cytokines such as IL-10, or a combination of the two. Therefore, in addition to the absolute concentrations of these cytokines, the relative concentrations of pro-and antiinflammatory cytokines can provide a useful index of the net inflammatory milieu and of immune dysregulation. In keeping with this hypothesis, it has been demonstrated that in comparison with control subjects, depressed subjects manifest significantly lower serum IL-10 concentrations, nonsignificantly higher IL-6 concentrations, and significantly higher IL-6 to IL-10 ratios (Dhabhar *et al.* 2009). Furthermore, higher levels of depressive

symptoms were significantly related to lower IL-10 concentrations and tended to be related to higher IL-6 to IL-10 ratios but were not significantly related to IL-6 concentrations across the total sample of participants (Dhabhar *et al.* 2009). Moreover, control subjects showed a strong positive correlation between serum IL-6 and IL-10 concentrations, which was completely absent (near-zero effect size) in depressed subjects. Although depressed subjects had significantly higher BMIs than did the controls, covarying for BMI (or controlling for BMI) did not alter this finding (Dhabhar *et al.* 2009).

Given the antiinflammatory properties of glucocorticoids (Rhen and Cidlowski 2005), it might be expected that patients with depression who have decreased glucocorticoid sensitivity, as manifested by nonsuppression of cortisol on the dexamethasone suppression test (DST), would be especially likely to show signs of immune activation. Some evidence suggests that this is indeed the case. Compared with patients with depression who have normal in vivo glucocorticoid sensitivity, patients who are DST nonsuppressors show increased plasma concentrations of the acute-phase reactant a_1-glycoprotein, as well as increased in vitro mitogen-stimulated IL-6 production (Pace and Miller 2009; Sluzewska 1999).

Other Psychiatric Disorders and Immune Function

Evidence suggests that other stress-related neuropsychiatric conditions--including anxiety disorders, schizophrenia, PTSD, chronic fatigue syndrome, seasonal affective disorder, and fibromyalgia--may also be associated with immune activation and neuroinflammation (Chauhan *et al.* 2021; Dziabis and Bilbo 2022; Feng *et al.* 2020; Fonken *et al.* 2018; Heurich *et al.* 2022; Liu and Quan 2018), although these conditions have been less well characterized than MDD. Individuals with combat-related PTSD have been reported to demonstrate increased plasma concentrations of IL-1, increased CSF concentrations of IL-6, and increased expression of genes related to inflammation and NF-kB systems (Yang and Jiang 2020). PTSD following civilian disasters appears to be associated with elevated plasma concentrations of IL-6 and its soluble receptor (Maes *et al.* 1999b). PTSD following childhood abuse is associated with enhanced CMI responses (Altemus *et al.* 2003). Although they have not been found consistently (Maes *et al.* 1999b), both severity of symptoms and duration of illness have been reported to correlate positively with indices of immune activation in PTSD (R. Miller *et al.* 2001; Spivak *et al.* 1997).

A growing body of literature suggests that patients exposed to early-life trauma may be especially vulnerable to the development of psychophysical disorders (e.g., chronic fatigue syndrome, fibromyalgia) that are characterized by complaints of chronic pain, fatigue, and cognitive difficulties of unknown etiology (Heim *et al.* 1997). Consistent with this vulnerability, these disorders have also been associated with evidence of increased inflammatory activity. For example, it has been reported that both chronic fatigue syndrome and fibromyalgia are accompanied by an increase in acute-phase reactants and increased plasma concentrations and/or peripheral blood mononuclear cell production of proinflammatory cytokines, including IL-1, IL-6, and TNF-a (Borish *et al.* 1998; Cannon *et al.* 1999; Gupta *et al.* 1997; Maes *et al.* 1999a). Of note, one report indicates that seasonal affective disorder, a condition with significant symptom overlap with chronic fatigue syndrome and fibromyalgia, may be characterized by increased plasma concentrations of IL-6 (Leu *et al.* 2001).

Finally, there has been speculation that immune system activation may contribute to the pathophysiology of psychotic disorders, including schizophrenia, possibly related to an autoimmune diathesis (Pearce 2001; Rothermundt *et al.* 2001). Elevated levels of cytokines and their receptors, including IL-2, soluble IL-2, TNF, and IL-6, have been reported in the blood and CSF of patients with schizophrenia (Goldsmith *et al.* 2016), and a high level of CSF IL-2 has been found to predict subsequent schizophrenic relapse (Rothermundt *et al.* 2001). In a related fashion, on the basis of seasonal birth patterns that have been reliably replicated in large epidemiological studies of patients with schizophrenia, consideration has been given to the role of viral infection early in development (Pearce 2001). These findings are consistent with in utero infections of relevant brain structures, including the hippocampus, during critical periods of development (especially during the second trimester) (Pearce 2001). Moreover, cross-reactivity between brain antigens and antigens of infectious agents may contribute not only to schizophrenia but also to the neurological and psychiatric complications associated with streptococcal infection (i.e., pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections [PANDAS]) (Snider and Swedo 2000). Finally, microglial activation is reported to be involved in the context of schizophrenia (Izuo and Nitta 2021) and autism (Bilbo *et al.* 2018), and it has been suggested that immune mechanisms involving activation of the complement system and microglia contribute to psychiatric disorders by mediating synaptic dysfunction and/or loss (Stevens and Johnson 2021; Tenner *et al.* 2018).

Mediating Pathways

Underlying the ability of the CNS to affect the immune system is a host of connections between autonomic nervous system (ANS) and neuroendocrine pathways and immune system elements. Immune cells are able to directly respond to brain outflow pathways via receptors for small-molecule neurotransmitters, adrenal and gonadal steroids, hypothalamic-releasing factors, and other neuropeptides (Raison *et al.* 2002). Specific receptor densities vary among immune cell types, and these variations correlate with cell sensitivity to a given ligand.

Autonomic Nervous System

It is well known that sympathetic and parasympathetic pathways within the ANS interact to maintain homeostasis in a variety of physiological states, including regulation of the immune response. In addition to expressing receptors for autonomic and neuroendocrine signaling molecules, immune cells and tissues are innervated by fibers derived from the ANS, together forming a neural pathway that can reflexively regulate the immune response (Czura *et al.* 2007; Downing and Miyan 2000; Miller 1998; Raison *et al.* 2002; Sanders and Kavelaars 2007; Tracey 2002). The sympathetic branch of the ANS appears able to influence the immune system either by changing the vascular tone and blood flow into lymphoid organs or by directly influencing immune cell function via locally released neurotransmitters, especially norepinephrine, and neuropeptides such as neuropeptide Y, substance P, vasoactive intestinal peptide, calcitonin gene-related peptide, and CRH, which, in turn, interact with specific receptors on nearby immune cells (Bellinger *et al.* 1997; Czura *et al.* 2007).

In addition to immune regulation by the sympathetic branch, the parasympathetic branch of the ANS has been shown to contribute to the regulation of innate immune responses via an efferent neural signaling pathway referred to as the *cholinergic antiinflammatory pathway* (Tracey 2002). The existence of this pathway was initially identified in studies showing that stimulation of the vagus nerve attenuates immune system activation and the physiological signs of septic shock in response to lipopolysaccharide, a key component of gram-negative bacterial cell walls (Borovikova *et al.* 2000). Follow-up studies have determined that vagal release of acetylcholine, which in turn interacts with the a7 subunit of the acetylcholine receptor (a7nAChR) on relevant immune cells, is capable of suppressing production of cytokines, including TNF-a, via inhibitory effects on nuclear translocation of NF-kB (Altavilla *et al.* 2006; Guarini *et al.* 2003) and activation of JAK2 (Janus kinase 2)/STAT3 (signal transducer and activator of transcription 3) (de Jonge *et al.* 2005; Pavlov and Tracey 2005).

Subsequent investigations have established that cytokine production is inhibited by efferent vagal pathways in the context of a variety of inflammatory processes, including myocardial ischemia, hemorrhagic shock, ischemia/reperfusion, and pancreatitis (Altavilla *et al.* 2006; Guarini *et al.* 2003; Mioni *et al.* 2005; van Westerloo *et al.* 2006; Wang *et al.* 2004). It also has been shown that both vagus nerve stimulation and a7nAChR agonists inhibit production of a number of proinflammatory cytokines, including TNF, IL-1, IL-6, IL-8, and high-mobility group box 1 (Wang *et al.* 2004). Notably, a specific a nAChR-dependent vagus nerve pathway to the spleen has been identified that inhibits proinflammatory cytokine production during endotoxemia and polymicrobial sepsis. Furthermore, both splenectomy and vagotomy interrupt the cholinergic antiinflammatory response (Huston *et al.* 2006). Interestingly, on the basis of these findings, electrical stimulation by vagal afferents has been designated as a breakthrough treatment by the FDA for the treatment of rheumatoid arthritis (Pavlov *et al.* 2020). Of note, vagal nerve stimulation used to treat depression provides only efferent vagal nerve stimulation, although in a recent study, transcutaneous vagal nerve stimulation was found to decrease IL-6 and IFN-g in patients with PTSD (Bremner *et al.* 2020). Taken together, these findings suggest that in addition to effects on cellular signaling, there are anatomical and hard-wired components of the cholinergic antiinflammatory pathway that may have therapeutic relevance.

Hypothalamic-Pituitary-Adrenal Axis

In concert with the ANS, the HPA axis serves as a central component of the mammalian stress response system. Although glucocorticoids, which represent the final product of HPA axis activation, have long been viewed as immunosuppressive because of their well-documented ability to suppress inflammation (largely through protein-protein interactions between the glucocorticoid receptor and NF-kB) (Rhen and Cidlowski 2005), it is increasingly recognized that HPA axis effects on immunity are complex (Dhabhar 2009a, 2009b, 2014; Dhabhar *et al.* 1995). This complexity arises from the fact that HPA axis effects on the immune system depend on numerous factors, including the immune compartment that is being assessed, the element of the HPA axis being evaluated (i.e., CRH vs. cortisol), and the duration and timing relative to the immune response and stressor application. Thus, for example, glucocorticoids are known to mediate immune cell redistribution in the body (Dhabhar *et al.* 1996, 2012) and to enhance CMI in vivo (Dhabhar and McEwen 1996) through their effects on lymphocyte trafficking (Dhabhar 1998, 2009a, 2014). Moreover, different HPA axis elements demonstrate divergent immune system effects. For example, the end result of CRH-induced HPA axis activation is proinflammatory cytokine suppression, yet studies demonstrate that the direct effect of CRH on proinflammatory cytokine production may be stimulatory (Labeur *et al.* 1995; Paez Pereda *et al.* 1995).

Finally, the effect of glucocorticoids on naturalistic measures of immunity, such as cutaneous CMI, depends on both the concentration and the duration of glucocorticoids within the immune compartment under consideration. Thus, low doses of glucocorticoids applied for brief periods have been shown in rodents to stimulate CMI, whereas higher (or more protracted) glucocorticoid exposure suppresses CMI (Dhabhar 2009a, 2009b, 2014; Dhabhar and McEwen 1999).

CRH applied within the CNS suppresses several measures of immunity, including splenic NK cell activity, mitogen-stimulated lymphocyte proliferation, and in vivo and in vitro antibody formation, as well as T cell responses to T cell receptor antibody (Caroleo *et al.* 1993; Irwin *et al.* 1988; Labeur *et al.* 1995; Rassnick *et al.* 1994). In contrast to its immunosuppressive properties, CRH has also been shown to enhance proinflammatory cytokine production in rodents and humans when administered peripherally or within the CNS. Chronic intracerebroventricular administration of CRH to rats leads to induction of IL-1b messenger RNA (mRNA) in splenocytes, and acute intravenous administration in humans has been reported to cause a fourfold increase in the induction of IL-1a (Labeur *et al.* 1995; Schulte *et al.* 1994). In addition to potential proinflammatory activities of CRH within the CNS, peripheral production of CRH has been demonstrated in inflammatory diseases such as ulcerative colitis and arthritis, in which it appears to act as a local proinflammatory agent (Karalis *et al.* 1997; Nishioka *et al.* 1996).

Of all neurotransmitters or hormones known to modulate immune functioning, the actions of glucocorticoids, although complicated, are probably the best understood (Raison *et al.* 2002). Identified effects of glucocorticoids on the immune (and inflammatory) system include the following:

- Modulation of immune cell trafficking throughout the body (Dhabhar *et al.* 1995)
- Enhancement of CMI by physiological concentrations of endogenous glucocorticoids (Dhabhar 2009a, 2009b, 2014; Dhabhar and McEwen 1999)
- Promotion of Th2 (antibody) responses (Elenkov and Chrousos 1999)
- Modulation of cell death (i.e., apoptosis) pathways (McEwen *et al.* 1997)
- Inhibition of arachidonic acid pathway products (e.g., prostaglandins) that mediate inflammation and illness symptoms (e.g., fever) (Goldstein *et al.* 1992)
- Inhibition of T cell-and NK cell-mediated cytotoxicity (Raison *et al.* 2002)
- Inhibition of cytokine production and function through interaction of glucocorticoid receptors with transcription factors (NF-kB in

particular), which in turn regulate the expression of cytokine genes and/or cytokine-inducible genes (McKay and Cidlowski 1999)

Although glucocorticoids may actually enhance certain aspects of naturalistic immune functioning when produced for brief periods at low to moderate doses in the context of acute and/or mild stress, glucocorticoids in general play a primary role in restraining excessive or prolonged inflammatory activation (Munck 1989). This property has long been exploited by modern medicine for the treatment of autoimmune and other chronic inflammatory conditions, with the result that glucocorticoids remain a cornerstone of our antiinflammatory armamentarium. Consistent with their pharmacological uses, glucocorticoids have been shown to be essential for inflammatory regulation in response to immune system activation. For example, neutralization of endogenous glucocorticoid function results in increased pathology and mortality in rodents exposed to lipopolysaccharide or to other inflammatory stimulators such as streptococcal cell wall antigen or myelin basic protein (Bertini *et al.* 1988; Sternberg *et al.* 1989). Similarly, rodents that have been rendered glucocorticoid deficient by adrenalectomy have markedly increased death rates following infection with murine CMV, an effect that arises from unrestrained activity of the proinflammatory cytokine TNF (Ruzek *et al.* 1999). Relevant to chronic stress, increased inflammatory cytokines can also disrupt translocation of the glucocorticoid receptor from cytoplasm to the nucleus, leading to glucocorticoid resistance (Pace and Miller 2009).

Effects of the Immune System on the Brain and Behavior

Immune System-to-Brain Signaling Pathways

The field of psychoneuroimmunology is based on the existence of bidirectional communication pathways between the nervous and immune systems (Ader 2007; Miller *et al.* 2000). This bidirectionality implies that just as the CNS is capable of modulating immunity, the immune system can alter functioning within the CNS. Although researchers historically were interested in pathways by which the brain affects immunity, the past 20-30 years have seen a groundswell of interest in the ways in which the immune system contributes to the development of psychopathology (Capuron and Miller 2011; Steinberg *et al.* 2015).

Underpinning this growing interest is an increasing appreciation for the multiple ways in which inflammatory cytokines are able to signal the brain and change CNS function (Table 5-2). Although the brain was initially considered an "immune privileged" organ, protected from immune system activity by the blood-brain barrier, it is now clear that cytokines released in the periphery rapidly affect CNS functioning via multiple pathways (see Table 5-2) (Banks 2006; Banks *et al.* 1995; Maier *et al.* 1998; Plotkin *et al.* 1996; Quan 2006, 2014; Raison *et al.* 2002; Rivest *et al.* 2000). Moreover, immune cells are now known to patrol the brain through lymphatic vessels and the meninges, and increasing data indicate that the brain represents an immune system compartment that generates its own local immune environment, which serves as the backdrop for peripheral immune influences (Cugurra *et al.* 2021; Rustenhoven *et al.* 2021).

TABLE 5-2. **Evidence that cytokines can alter central nervous system function**

1. Cytokines released peripherally have access to the brain.
   * Passage through leaky regions or disruptions in the blood-brain barrier during stress
   * Active transport
   * Activation of intermediary cell types (e.g., endothelial cells) that produce relevant second messengers (e.g., prostaglandins, reactive nitrogen and oxygen species, cytokines)

    - * Transmission of cytokine signals through afferent nerve fibers (e.g., vagus)
    - * Entry of immune cells into the brain parenchyma
2. A cytokine network exists within the brain.
    - * Glia (especially microglia) and neurons express/produce cytokines and express cytokine receptors
    - * The glymphatic system allows local access by immune mediators to brain regions, especially those in proximity to the CSF.
3. Cytokines have effects on neurotransmitter turnover, neuroendocrine function, synaptic plasticity, neurocircuitry, and behavior.

Once inflammatory cytokine signals gain access to the CNS, the signal is amplified by a cytokine network within the brain itself (Quan *et al.* 1999). Receptors for inflammatory cytokines are found throughout the brain, especially in subcortical regions including the striatum, which play a pivotal role in integrating neurotransmitter inputs that regulate motivation and motor activity, but also including the insula, dorsal anterior cingulate cortex (dACC), amygdala, hippocampus, and hypothalamus, which

play important roles in emotion regulation and homeostasis. Among neural cells, activated microglia are capable of producing inflammatory cytokines and nitrogen and oxygen radicals, which in turn are potent activators of other glial elements including astrocytes and oligodendrocytes (Miller and Raison 2016; Schobitz *et al.* 1994). Of interest, growing evidence suggests that nonimmunological stressors can also induce cytokine expression in the brain, an effect likely mediated by stress-induced activation of microglia in part related to reduced neuronal production of fractalkines that regulate reactive microglia (Frank *et al.* 2007; Weber *et al.* 2017). These data suggest that CNS cytokine pathways may participate in an organism's response to a wide variety of environmental perturbations.

Inflammation and Depression

A rich database indicates that inflammation may play a role in the development of multiple psychiatric disorders, including MDD, which has been the most studied in this regard (Beurel *et al.* 2020; Miller and Raison 2016). As noted earlier in this chapter, patients with MDD exhibit all the cardinal features of a chronic inflammatory response, including increases in peripheral blood and CSF inflammatory cytokines, acute-phase reactants, chemokines, and cellular adhesion molecules. Meta-analyses of this literature indicate that peripheral blood concentrations of IL-6, IL-1, and TNF, along with CRP, are the most reliably elevated in this regard (Dowlati *et al.* 2010; Howren *et al.* 2009). In addition, there is evidence of increased inflammation in the brain, as reflected by increased inflammatory signaling molecules such as toll-like receptors in brain parenchyma (Pandey 2017), activation of microglia, and evidence of immune cell trafficking to brain perivascular regions and the meninges (Miller and Raison 2016; Setiawan *et al.* 2015; Torres-Platas *et al.* 2014). A second major body of data that indicates that there is a link between inflammation and depression is that the administration of inflammatory cytokines such as interferon-a (IFN-a) (used for the treatment of cancer and infectious diseases), as well as inflammatory stimuli, including endotoxin and typhoid and influenza vaccinations (typically given to healthy volunteers), leads to the development of depressive symptoms (Miller and Raison 2016; Miller *et al.* 2013). Moreover, inhibition of inflammation can reduce depressive symptoms. These latter findings are most apparent in patients with autoimmune and inflammatory disorders administered anticytokine therapies (Kappelmann *et al.* 2018), although, as indicated below, there is some evidence that antiinflammatory drugs, including anticytokine therapies, may reduce depressive symptoms in patients with depression who are otherwise medically healthy (Kohler-Forsberg *et al.* 2019). Additional evidence of a relationship between inflammation and depression is the observation that rates of depression are significantly elevated in a wide variety of medical conditions, including inflammatory and autoimmune disorders such as multiple sclerosis and rheumatoid arthritis, as well as in illnesses such as cardiovascular disease, diabetes, and cancer, which are increasingly being recognized as having an inflammatory component (Aggarwal *et al.* 2006; Blake and Ridker 2002; Currier and Nemeroff 2014; Dantzer *et al.* 2008, 2011; Evans *et al.* 2005). Finally, increased inflammatory markers, including CRP and IL-6, have been found to reliably predict the development of depression in longitudinal studies (Mac Giollabhui *et al.* 2020; Raison *et al.* 2006).

It should be noted that psychiatric disorders such as depression are not inflammatory disorders per se, and inflammation is increased only in a subgroup of depressed patients (approximately 30% depending on the sample) (Osimo *et al.* 2019). The relative presence of inflammation is determined in part by other mitigating factors that can drive inflammatory responses, including obesity, stress (especially early-life stress), older age, chronic medical illnesses, dysbiosis, infection, and trauma (Lucido *et al.* 2021). Moreover, as mentioned earlier in this chapter, increased inflammation in association with behavioral changes is seen in multiple psychiatric disorders, including mood disorders, anxiety disorders, PTSD, and schizophrenia (Goldsmith *et al.* 2016). In general, based on our understanding of the effects of inflammation on the brain and behavior, inflammation-induced behavioral changes are not specific to any one disorder. Indeed, they are agnostic to diagnosis and truly transdiagnostic in nature (Lucido *et al.* 2021). As described below, inflammation leads to relatively specific effects on neurotransmitter systems, neurocircuits, and ultimately symptoms across disorders.

Pathways by Which Inflammation Produces Depression and Neuropsychiatric Disturbance

Given the substantial amount of data indicating that inflammation and depression have a cause-and-effect relationship (as evidenced by the induction of depressive symptoms by inflammatory stimuli and the reversal of depressive symptoms by antiinflammatory drugs in patients with increased inflammation), much attention has been paid to the potential mechanisms involved. Research to date has provided convincing evidence that the impact of inflammation on the brain is mediated through effects on the neurotransmitter systems and neurocircuits that are involved in behaviors reliably associated with depressive disorders, including alterations in motivation and motor activity as manifested by anhedonia and psychomotor retardation, as well as symptoms of anxiety, arousal, and alarm (Miller *et al.* 2013) (Table 5-3; Figure 5-2).

FIGURE 5-2. Pathophysiological pathways from inflammation to the brain and behavior.

Multiple predisposing factors including early-life stress (ELS), metabolic derangements, infection, and illness can drive inflammatory signaling pathways involving nuclear factor kB (NF-kB) and the inflammasome in immune cells such as monocytes, which in turn undergo metabolic reprogramming, including a shift from oxidative phosphorylation (OX PHOS) to glycolysis. Activated immune cells (e.g., macrophages) then produce inflammatory cytokines that access the brain and influence neurotransmitter systems, including dopamine (DA) and glutamate (Glu), in the striatum, thereby disrupting functional connectivity of the striatum to the ventromedial prefrontal cortex (vmPFC) and supplementary motor area (SMA). These effects on neurocircuitry lead to behavioral alterations such as decreased effort-based motivation, anhedonia, and psychomotor slowing. Inflammatory cytokines can also engage neurocircuits involving the dorsal anterior cingulate cortex (dACC), insula, hippocampus, and amygdala, leading to behavioral states characterized by anxiety, arousal, and alarm.

Effects of Inflammation on Monoamine Neurotransmitters, Glutamate, and Growth Factors

Inflammatory mediators, including inflammatory cytokines, have been shown to decrease the synthesis and release and increase the reuptake of the monoamine neurotransmitters serotonin, norepinephrine, and dopamine. Regarding synthesis, inflammation has been shown to decrease the availability of tetrahydrobiopterin (BH4), which is an essential enzyme cofactor for all of the enzymes responsible for the synthesis of the monoamines as well as nitric oxide (NO) synthase (Felger *et al.* 2013a; Haroon *et al.* 2012). In the context of inflammation and activation of NO synthase, BH4 is converted to BH2 in the production of NO, which plays a pivotal role in pathogen clearance and wound healing. Studies in humans with increased inflammation have shown decreased BH4 activity as manifested by an increase in the phenylalanine-to-tyrosine ratio, given the role of BH4 in supporting the activity of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine (Felger *et al.* 2013a). In addition, in patients treated with IFN-a, an increase in the phenylalanine-to-tyrosine ratio was found in association with depressive symptoms and decreased CSF dopamine, and decreased CSF BH4 was associated with increased CSF IL-6 (Felger *et al.* 2013a). Interestingly, the conversion of BH2 to BH4 can be promoted by folic acid, L-methylfolate, and *S*-adenosyl methionine (SAMe), and L-methylfolate was found to be effective in the treatment of antidepressant nonresponders, but only those with evidence of increased inflammation and BMI at baseline (Shelton *et al.* 2015). In terms of monoamine release, studies in laboratory animals have reliably demonstrated that inflammatory cytokines can decrease the release of dopamine in the striatum in association with reduced effort-based motivation (Felger *et al.* 2013b). Of note, no effects were found in the ability to experience pleasure, which is primarily mediated by opioid signaling pathways. The mechanism of these effects on monoamine release remains unclear, although there is some evidence that effects on the vesicular monoamine transporter may be involved. Finally, inflammatory cytokines including TNF and IL-1b have been shown to increase both expression and function of monoamine reuptake transporters, leading to decreased monoamine availability in the synapse, which in turn has been associated with depressive-like behaviors in rodents exposed to endotoxin (Zhu *et al.* 2010).

Another major neurotransmitter affected by inflammation is glutamate. Glutamate is the major excitatory neurotransmitter in the brain, and its concentration is carefully controlled to avoid toxicity and local and regional brain dysfunction (Haroon *et al.* 2017). Inflammatory mediators, including inflammatory cytokines, have well-established effects on astrocytes that lead to a buildup of synaptic glutamate, including decreasing the excitatory amino acid transporters that remove glutamate from the synapse and inducing reverse efflux of glutamate from these transporters, leading to increased release of glutamate from the xC transporter in the process of producing glutathione to combat inflammation-induced oxidative stress (Haroon *et al.* 2017). These effects can lead to excessive synaptic glutamate that can spill over into the extrasynaptic space and bind to extrasynaptic glutamate receptors, which can lead to decreased production of growth factors such as brain-derived neurotrophic factor (BDNF) and ultimately excitotoxicity (Haroon *et al.* 2017). Of note, inflammation--including IL-1b and its signaling pathway NF-kB--has been shown to have direct effects on BDNF production and neurogenesis (Koo *et al.* 2010). Activated microglia can also produce glutamate, further exacerbating the impact of inflammation on glutamate regulation (Haroon *et al.* 2017). Studies using magnetic resonance spectroscopy in humans receiving IFN-a or depressed patients manifesting increased inflammation have demonstrated increased glutamate in the dACC and basal ganglia (including striatum) in association with disruption in the coherence and precision of local neuronal firing and functional connectivity throughout the brain as well as behavioral changes including anhedonia and treatment nonresponse (Haroon *et al.* 2014, 2016, 2018a).

Taken together, inflammatory cytokines can reduce monoamine availability and increase glutamate while reducing BDNF and neurogenesis, leading to depression. These effects may in turn undermine treatment response to conventional antidepressants, whose efficacy relies on increasing synaptic monoamines and increasing BDNF-induced neurogenesis, while having no substantial effect on glutamate, thereby contributing to antidepressant treatment resistance (see subsection "Treatment Implications of Inflammation Effects on the Brain" below) (Raison *et al.* 2013a).

Effects of Inflammation on Neurocircuitry

In conjunction with studies examining the impact of inflammation on neurotransmitter systems and growth factors in the brain, a variety of neuroimaging strategies have been used to examine the impact of inflammation on neurocircuitry. Studies have included those in which subjects are exposed to inflammatory stimuli, as well as a smaller number of studies examining the relationship between endogenous inflammation and brain neurocircuitry. In general, two major targets of inflammation have been reliably characterized: subcortical (striatum) and prefrontal cortical brain regions involved in motivation and motor activity, and threat circuitry involving the amygdala, insula, dACC, and hippocampus (Miller and Raison 2016; Miller *et al.* 2013). For example, in separate studies conducted in independent laboratories, IFN-a, endotoxin, and typhoid vaccination have all been found to decrease activation of the ventral striatum in association with depressive symptoms, including decreased motivation (Capuron *et al.* 2012; Eisenberger *et al.* 2010; Harrison *et al.* 2016). Of note, the ventral striatum is the same brain region where reliable inflammation-induced decreases in dopamine and increases in glutamate were observed, and these two neurotransmitters are well known for their role in reward processing and motor activity (Felger *et al.* 2013b; Haroon *et al.* 2016). In addition, increased endogenous inflammation as reflected by elevated CRP has been shown to correlate with reduced functional connectivity between the ventral striatum and the ventromedial prefrontal cortex in conjunction with anhedonia. Increased endogenous inflammation has also been associated with reduced functional connectivity involving dorsal striatal regions in relation to decreased psychomotor speed (Felger *et al.* 2016). Regarding threat circuitry, a recent study showed increased amygdala reactivity following IFN-a administration to patients with hepatitis C and decreased amygdala reactivity following administration of infliximab to patients with autoimmune and inflammatory disorders (Davies *et al.* 2020). Several studies have also shown increased activation of the dACC in association with inflammation and hypersensitivity to social threat and error processing (Capuron *et al.* 2005; Slavich *et al.* 2010). Although potentially contributing to psychiatric symptoms in modern times, these effects of inflammation on motivation and motor activity as well as arousal, anxiety, and alarm are believed to have subserved survival priorities in ancestral times to allow conservation of energy resources for fighting infection and wound healing (via reduced exploratory activity) as well as provoking hypervigilance to protect a wounded or infected defenseless animal from attack (Raison and Miller 2013).

Effects of Inflammation on Glucose and Lipid Metabolism, the Kynurenine Pathway, and Glucocorticoid Receptor Function

Additional pathways, including the metabolism of glucose and lipids as well as activation of the kynurenine pathway, appear to contribute to the effects of inflammation on behavior. In terms of cellular metabolism, there has been increasing interest in the role of immune cell metabolism, or immunometabolism, as an important mechanism related to the impact of inflammation on the brain (Treadway *et al.* 2019). Indeed, when immune cells become activated, they shift their metabolism from the energy-efficient oxidative phosphorylation to the energy-inefficient glycolysis. This so-called Warburg effect puts a marked energy demand on the body, and in the context of immune activation, inflammation can account for up to 30% of the daily energy expenditure, greatly reducing the energy available for other activities (Straub 2017). Interestingly in this regard, anhedonia, specifically the unwillingness to expend effort for reward, in depressed patients with increased inflammation is associated with activation of signaling pathways associated with glycolysis, suggesting that both a metabolic shift toward glycolysis and inflammation, in some combination, are involved in the expression of anhedonia (Bekhbat *et al.* 2020). In a related fashion, the treatment response to the TNF antagonist infliximab is predicted by gene expression pathways overrepresented by gluconeogenesis and lipid metabolism, and treatment responders to infliximab exhibit decreased plasma lipids following infliximab administration (Bekhbat *et al.* 2018; Mehta *et al.* 2013). Similar results have been found with symptoms of psychomotor retardation (Bekhbat *et al.* 2021), and in patients with depression, markers of impaired glucose metabolism are associated with decreased functional connectivity between the ventral striatum and ventromedial prefrontal cortex, but only in patients with high inflammation (Goldsmith *et al.* 2020). Motivational deficits and negative symptoms in patients with schizophrenia are also associated with increased plasma lipids, but only in patients with high inflammation (Goldsmith *et al.* 2021). Taken together, these data suggest that there is an interaction between metabolic shifts in both cellular and systemic immunometabolism and inflammation that leads to behavioral changes related to motivation and motor activity.

The kynurenine pathway has also been implicated as a potential mediator of the effects of inflammation on the brain and behavior. Inflammatory stimuli, including TNF and IFN-g, activate the enzyme indoleamine 2,3 dioxygenase (IDO) in monocytes and dendritic cells (Haroon *et al.* 2020). Upon activation, IDO converts tryptophan

to kynurenine, which can be transported to the brain by the large neutral amino acid transporter (Haroon *et al.* 2020). Once in the brain, kynurenine is converted to kynurenic acid by astrocytes and quinolinic acid by microglia. Quinolinic acid can bind to extrasynaptic *N*-methyl-D-aspartate receptors, leading to excitotoxicity. Quinolinic acid can also cause astrocytes to increase release and decrease reuptake of glutamate, further contributing to excessive glutamate as a result of inflammation (Haroon *et al.* 2020). Activation of the kynurenine pathway as evidenced by an increased kynurenine-to-tryptophan ratio has been associated with increased glutamate in the basal ganglia as well as decreased regional homogeneity and functional connectivity in multiple brain regions in association with anhedonia and treatment nonresponse (Chen *et al.* 2021). Interestingly, competitive blockade of the large neutral amino acid transporter by leucine following administration of endotoxin has been shown to abrogate depressive-like behavior in mice (Walker *et al.* 2019). These data indicate that the kynurenine pathway may be a relevant target for treatment development in individuals with increased inflammation. Of note, there appears to be a special relationship between activation of the kynurenine pathway and suicide, suggesting that such treatment development may be particularly relevant for psychiatric patients with increased inflammation and suicidal ideation (Brundin *et al.* 2016).

Although there are homeostatic regulatory mechanisms available in the body to modulate inflammatory responses, one of the most potent of these, glucocorticoids, are rendered ineffective by the effects of inflammation on the glucocorticoid receptor. Indeed, as noted above, inflammatory cytokines have been shown to decrease the translocation of the glucocorticoid receptor from cytoplasm to nucleus through activation of p38 MAPK (mitogen-activated protein kinase) signaling pathways. Other inflammatory signaling pathways--including NF-kB, Jun amino (N)-terminal kinase (JNK), and STAT5--have also been shown to alter glucocorticoid receptor function (Pace *et al.* 2007). Thus, inflammatory cytokines can contribute to a state of glucocorticoid resistance, which has been well described in depressed patients and can lead to a feedforward cascade of stress and inflammation in depression and other psychiatric disorders, including anxiety disorders and PTSD.

Treatment Implications of Inflammation Effects on the Brain

Given the detailed understanding of how inflammation can influence the brain to change behavior, there has been considerable interest in testing antiinflammatory drugs in the populations of patients that exhibit increased inflammation. The majority of studies have included patients with depression as well as patients with schizophrenia. While the results provide some promise of modest effects, there are a number of limitations of the clinical trials that have been conducted to date, complicating the interpretation of the findings.

A number of medications with antiinflammatory properties have been explored in depression and schizophrenia, including cytokine antagonists; cyclooxygenase inhibitors such as aspirin and other nonsteroidal antiinflammatory drugs; minocycline, a microglial stabilizer and antibiotic; statins; glucose-lowering drugs such as pioglitazone; omega-3 fatty acids; and glucocorticoids. Meta-analyses of this literature indicate that these medications are generally well tolerated and provide modest improvement in depressive symptoms (Kohler-Forsberg *et al.* 2019). However, many of the trials were of small size, and few targeted patients with increased inflammation specifically. Given that only about one-third of depressed patients exhibit increased inflammation, these findings should be interpreted with caution. Indeed, the largest trial to date, which included depressed patients treated with minocycline, the cyclooxygenase inhibitor celecoxib, or placebo, showed no difference among or between treatment groups (Husain *et al.* 2020). As with other trials, however, this study did not stratify patients on the basis of inflammatory status. Population-based studies examining much larger sample sizes have failed to find reliable efficacy of antiinflammatory agents, largely cyclooxygenase inhibitors, in preventing depression (Berk *et al.* 2020). Nevertheless, one large study in cancer patients did see a significant effect of aspirin in reducing depressive symptoms (Hu *et al.* 2020). Of note, cancer patients are well known to exhibit increased inflammation by virtue of their cancer and its treatment. In terms of schizophrenia, meta-analyses examining the effects of celecoxib and minocycline have revealed evidence of safety and modest efficacy as an adjunct to antipsychotic therapy (Xiang *et al.* 2017). Nevertheless, as with similar studies in depression, sample sizes were small, and the patients were not selected based on inflammatory status. Taken together, the data on antiinflammatory agents for depression and schizophrenia, while promising, are difficult to interpret given the clinical trial designs and the limited sample sizes. These limitations will be discussed in more detail below.

Another important translational observation regarding the impact of inflammation on the treatment of psychiatric disease is that increased inflammation is associated with treatment nonresponse, especially in patients with MDD. Increased inflammatory biomarkers prior to antidepressant treatment predict treatment nonresponse (Strawbridge *et al.* 2015), and depressed patients who have failed to respond to multiple antidepressant treatment trials are more likely to exhibit increased inflammatory markers (Haroon *et al.* 2018b). Furthermore, many of the clinical predictors of poor response to antidepressant treatment, including obesity, childhood maltreatment, anxiety disorders, PTSD, and OCD, have been associated with increased inflammatory biomarkers (Miller *et al.* 2009). Interestingly, increased inflammatory biomarkers, including IL-6, have been shown to predict response to alternative antidepressant therapies, such as ketamine and electroconvulsive therapy (Lucido *et al.* 2021). Moreover, at least two studies have demonstrated that increased inflammation (as reflected by a CRP level > 1 mg/L) predicts a poor response to the serotonin reuptake inhibitor escitalopram and a much better response to drugs that affect dopamine, such as bupropion and nortriptyline, the latter of which has been shown to increase dopamine in the prefrontal cortex (Lucido *et al.* 2021). The better response to dopaminergic drugs predicted by biomarkers of increased inflammation is consistent with the effects of inflammation on dopamine in reward pathways. These findings suggest that measuring inflammatory biomarkers such as CRP prior to treatment might help guide antidepressant choice, with a preference for dopaminergic therapies in patients with high inflammation as opposed to serotonin reuptake inhibitors (Lucido *et al.* 2021).

Finally, it should be noted that there is a literature on the effects of antidepressant and antipsychotic medications on immune responses, including inflammation. Although antiinflammatory effects have been observed with both classes of medications in vitro and in vivo, the literature is somewhat mixed, and it remains unclear whether this immune activity is related to the clinical efficacy of these medications.

Given what we know about brain-immune system interactions, there are many opportunities to optimize future clinical trials to ensure that any effects of antiinflammatory strategies, if they exist, will be revealed (Miller and Raison 2015, 2016). To date, few studies have stratified patients by level of inflammation, and few studies have examined target engagement by the antiinflammatory drug, such as by inhibiting inflammation and then correlating the inhibition with treatment response. Importantly, no study has used what we know about the neurotransmitters and neurocircuits affected by inflammation to adjust outcome variables to reflect the most common inflammation-related symptoms, including anhedonia. Indeed, all three studies that used anticytokine therapies to treat patients with depression found a consistent effect on anhedonia (Lee *et al.* 2020; Raison *et al.* 2013b; Salvadore *et al.* 2018). Taken together, these shortcomings have prompted a series of recommendations to guide future clinical trials. First, clinical trials should either stratify patients into high-and low-inflammation groups (with the hypothesis that only the high-inflammation group should respond to an antiinflammatory intervention) or only include patients with increased inflammation. Second, a measure of target engagement should be provided, notably a biomarker of inflammation either in the brain or at the periphery, that demonstrates that inflammation indeed has been inhibited in those with increased inflammatory markers at baseline. Biomarkers in this regard may also include neurotransmitter systems or neurocircuits that are known to be affected by inflammation. Changes in biomarkers should in turn be correlated with changes in relevant symptoms. Third, primary outcome variables should include objective and clinical measures of symptoms that are known to be associated with inflammation and its effects on the brain, notably anhedonia. Given that studies to date have not taken advantage of the opportunities provided by a specific pathophysiological pathway that is being targeted in psychiatric patients, most of the data we have hails from traditionally designed clinical trials in which heterogeneous groups of patients are administered a drug with the hope that there will be some nonspecific overall response. The role of inflammation in neuropsychiatric disease provides a new path that eschews outdated trial designs and moves toward more precision-based studies derived from our understanding of the specific pathophysiology involved.

Conclusion

It is important to appreciate that mental and physical health are maintained through multidirectional interactions among psychological factors and the nervous, endocrine, and immune systems and other physiological systems of the body. Thus, it should come as no surprise that dysregulated multisystem interactions are often involved in mediating the underlying pathology of numerous diseases. In this chapter we have reviewed a few important examples of ways in which the nervous and endocrine systems affect immune function and the ways in which the immune system in turn affects the nervous system and behavior in the context of health and disease. Much work remains to be done to further elucidate mechanisms and translate findings from bench to bedside. However, elucidation of brain-immune system pathways and mechanisms is likely to be critically useful for restoring health in the presence of disease or promoting health in the absence of disease.

CHAPTER 6

Pharmacokinetics, Pharmacodynamics, and Pharmacogenomics

Joseph F. Goldberg, M.D.

This chapter addresses core concepts about the mechanics of how the body processes psychotropic medications, with a focus on pragmatic clinical applications. As the modern pharmacopoeia continues to expand, clinicians find themselves with an ever-increasing range of medication options to treat psychiatric disorders in all their diversity--from complex and treatment-resistant to comorbid presentations across varied dimensions of psychopathology. Never has it been more critical for practitioners to recognize the mechanistic rationales behind psychotropic drugs, or their safe and reasonable use either alone or in deliberate combinations intended to target specific symptom constellations. Given the increasing interest and emerging database on the possible genetic determinants of drug treatment outcomes, this chapter will also highlight current information about the evidence base for or against pharmacogenomic testing, focusing on its strengths and limitations as a clinical tool for practicing psychopharmacologists.

Basic Definitions

Pharmacokinetics refers to the effects of the body on a drug; *pharmacodynamics* refers to the effects of a drug on the body. *Bioavailability* refers to the proportion of an administered drug that enters the circulatory system and is available for uptake by site-of-action organs; it can be operationally defined by comparing the ratio of the areas under the curve (AUCs) for blood concentration versus time for the extravascular versus intravascular formulations of a given compound. Drugs that are intravenously administered are, by definition, 100% bioavailable. Drugs that are administered by all other routes generally have diminished bioavailability by virtue of *first-pass effects*. (Indeed, drugs that undergo extensive first-pass metabolism, such as ramelteon, have

extremely low oral bioavailability.) First-pass metabolism occurs predominantly in the liver but also in the intestinal epithelium (e.g., by localized catabolic enzymes such as cytochrome P450 [CYP] 3A4) and, to some degree, the lungs and circulatory system/vascular endothelium. Intranasal, inhaled, sublingual, intramuscular, and transdermal drug administration routes often yield higher bioavailability than oral administration because first-pass hepatic metabolism is at least partly avoided.

Note also the concept of *bioequivalence*, which involves establishing comparable bioavailability across different drug formulations--that is, demonstrating a similar rate and extent of drug availability at the intended site of action. Bioequivalence is particularly relevant when one is comparing generic versus branded drug formulations, or one branded version with another. The World Health Organization, as well as the FDA, consider two agents to have bioequivalence if the 90% confidence interval of their relative plasma level AUCs and C_{max} distributions (as defined below) fall within 80%-125% of each other. This rather wide range means that it is possible for some drugs with more variable bioavailability to show more heterogeneous effects (yet still fall within acceptable standards) when a switch is being made from a branded to a generic formulation. Therefore, drug efficacy and possible adverse effects can differ between a generic and a branded drug formulation, as has been shown in the case of carbamazepine and levothyroxine, as well as for some manufacturers' generic formulations of bupropion XL 300 mg.

Pharmacokinetics entails four main physiological functions--absorption, distribution, metabolism, and elimination.

Absorption

Absorption refers to the process by which a metabolically active foreign compound (a xenobiotic) is introduced into the body (orally, parenterally, intramuscularly, intrathecally, transdermally, topically, sublingually, or by inhalation) and is available to enter the circulatory system for transport to an intended site of action. Absorption may be *zero-order* (constant, as occurs during an intravenous ketamine infusion for major depressive disorder [MDD]) or *first-order* (where the rate of absorption follows a linear trajectory that is proportional to the amount of drug not yet absorbed, as occurs with most oral medications). Once orally administered drugs become solubilized in the gastrointestinal tract, they can enter the systemic circulation by one of four mechanisms: 1) passive diffusion (occurring for low-molecular-weight drugs driven by a high-to-low concentration gradient across a membrane); 2) facilitated (carrier-mediated) passive diffusion (involving transport from *low* to *high* concentration gradients [e.g., glucose]); P-glycoprotein is an example of a transporter protein that extrudes toxins back into the gut intestinal lumen, as well as across the blood-brain barrier; 3) active transport; or 4) pinocytosis. Passive diffusion depends on a parameter known as the *lipid-water partition coefficient* (K_p), defined as the ratio of drug in the lipid phase versus the aqueous phase, with high K_p values reflecting high drug solubility. Factors that influence absorption include the route of administration, drug solubility, and rate of gastric emptying. Certain parameters are worth noting regarding the absorption of specific psychotropic agents. Gabapentin, for example, is absorbed from the intestines by an active transport mechanism that becomes saturated at doses greater than 1,200 mg at any one time. A proprietary once-daily gastroretentive formulation (Gralise) permits absorption of higher doses, while gabapentin enacarbil has about twice the oral bioavailability of immediate-release gabapentin and is absorbed through a different, less-saturable transport mechanism.

Distribution

Distribution refers to the process by which a drug is transferred from the systemic circulation to site-of-action organs. Some psychotropic drugs are transported from their site of absorption to their site of action via carrier proteins in the circulatory system (mainly albumin, but potentially also globulins or lipoproteins). Notable examples include diazepam or divalproex. Ultimately, unbound or free fractions of a drug are able to diffuse through capillary walls. In patients with low serum albumin levels (e.g., due to hepatic dysfunction, malnutrition, or increased albumin degradation due to renal impairment), it can be useful to measure the unbound fraction of a drug that is ordinarily highly protein bound in order to obtain a physiologically more accurate estimate of bioavailable drug, as illustrated in Clinical Vignette 1 below. Highly protein-bound drugs tend to have low metabolic clearance.

Clinical Vignette 1

A 154-pound 26-year-old man hospitalized for bipolar mania was orally loaded with divalproex extended release (divalproex ER) at 25 mg/kg once daily, yielding a projected therapeutic dosage of 1,750 mg/day, intended to produce a trough plasma valproate level between 85 and 125 mg/mL. A Day 5 trough valproate level was subtherapeutic at 31 mg/mL. A comprehensive metabolic profile revealed a low serum albumin level of 2.2 g/dL (laboratory reference range: 3.4-5.4 g/dL). A free serum valproic acid level was ordered and found to be in the high end (18 mg/mL) of the laboratory reference range (6-22 mg/mL). There were no clinical signs of gastrointestinal or neurological toxicity (e.g., nausea/vomiting or tremor and ataxia, respectively) and, accordingly, dosing was not changed. Workup of hypoalbuminemia revealed no evidence of renal disease/proteinuria, chronic medical disease, hepatic dysfunction, burns, or obvious malnutrition. However, anti-tissue transglutaminase IgA antibody testing was positive, consistent with a diagnosis of celiac disease, accounting for likely malabsorption as the cause of his hypoalbuminemia. The patient was referred for further gastrointestinal workup as his psychiatric symptoms improved with no further change to his regimen.

Metabolism

Drugs that undergo metabolism do so either through enzymatic degradation in the liver through phase I (consisting of CYP isoenzymes), which involves mainly oxidation, or phase II hepatic metabolism (described further in the section "Phases of Drug Metabolism"). Some CYP metabolic reactions also occur outside the liver; for example, CYP3A and CYP2C are found not only in the liver but also in the intestinal mucosa (Thelen and Dressman 2009). Gut CYP3A4 is rapidly and irreversibly inhibited by dietary CYP3A4 inhibitors such as grapefruit juice. Some drugs also undergo no metabolism and are simply eliminated unchanged in urine and/or feces (e.g., lithium, gabapentin).

Elimination

Drugs are eliminated from the body mainly either via renal excretion or by excretion into the bile (usually without undergoing hepatic metabolism), with subsequent passages into feces. Trace amounts of drugs are also eliminated through sweat, breast milk, saliva, or exhaled air. Renal excretion is the dominant mode of elimination for most psychotropic drugs and depends on intact kidney function. Renal function is traditionally measured by the glomerular filtration rate (GFR), which in turn is estimated (eGFR) from the patient's creatinine clearance (CrCl).

eGFR was formerly estimated using the Cockroft-Gault equation, which has fallen into disfavor for clinical (nonresearch) purposes because a) it does not take into account body surface area, and b) it has not been expressed using standardized creatinine values. The Cockroft-Gault equation has largely been replaced by either the Modification of Diet in Renal Disease (MDRD) equation (Levey *et al.* 1999) or the Chronic Kidney Disease-Epidemiology Collaboration (CKD-EPI) equation (Levey *et al.* 2009):

MDRD $$\text{eGFR} = 175 \times (S_{cr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}),$$

where S_{cr} is serum creatinine in mg/dL and Age is in years.

CKD-EPI $$\text{eGFR} = 141 \times \min(S_{cr}/k, 1)^{a} \times \max(S_{cr}/k, 1)^{-1.209} \times 0.993^{\text{Age}} \times (1.018 \text{ if female}) \times (1.159 \text{ if African American}),$$

where S_{cr} is serum creatinine in mg/dL, k is 0.7 for females and 0.9 for males, a is -0.329 for females and -0.411 for males, min indicates the minimum of S_{cr}/k or 1, max indicates the maximum of S_{cr}/k or 1, and Age is in years.

A normal eGFR is approximately 97-137 mL/min in men and 88-128 mL/min in women. GFR declines by about 10 mL/min for every decade after age 40 and also depends on weight. Some authors have noted that serum creatinine may be a less sensitive measure for milder degrees of renal insufficiency, or may be less accurate because of artificially elevated serum creatinine levels in certain populations (e.g., body builders who regularly lift weights or consume creatine ethyl ester supplements); cooked meats also convert skeletal muscle creatine to creatinine, and ingestion within 12 hours of measuring serum or urine creatinine levels has been shown to significantly increase measurable amounts (Nair *et al.* 2014). Serum cystatin C, a low-molecular-weight renally filtered protein, is sometimes measured as an alternative to serum creatinine in estimating (or corroborating) true GFR (Shlipak *et al.* 2013).

A drug's elimination is closely linked with its metabolism. Useful parameters for understanding drug exposure and elimination include the following:

Area under the curve (AUC): a graphical plotting of the plasma concentration of a drug (along the y-axis) by time (along the x-axis).

C_{max}: the maximal concentration of a drug, reflecting both the rate and the extent of absorption of that drug. C_{max} is highly correlated with AUC. Some authors suggest that the ratio of C_{max} to AUC is more useful than C_{max} alone for estimating bioequivalence of absorption rates across compounds (Endrenyi *et al.* 1991).

C_{min}: the minimal blood concentration of a drug, or trough level, as measured just before a next dose occurs.

For some orally administered drugs, C_{max} and AUC can both be affected by the presence or absence of food, as noted for specific compounds listed in the pharmacokinetic tables included at the end of this chapter.

Kinetics of Drug Elimination

Biological half-life refers to the time necessary for a drug either to a) reach half of its steady-state serum concentration (C_{ss}) or b) become reduced by half of its C_{ss} (termed *elimination half-life*). As a rule of thumb, the passage of five half-lives is necessary in order for a drug either to achieve C_{ss} once it has been introduced or to become fully eliminated from the circulatory system. There are a number of caveats attached to the concept of the passage of five half-lives. First, some drugs can exert meaningful biological activity without the need to reach C_{ss}. For example, in the case of some second-generation antipsychotics with long half-lives and/or availability in the form of long-acting injectables, such as aripiprazole or risperidone, achievement of a clinically meaningful serum level (i.e., the threshold of 150-300 ng/mL [Kirschbaum *et al.* 2008]) occurs within several days after administration (even though C_{ss} may take at least 2 weeks to achieve). Second, the concept of half-lives is more directly relevant to drugs that bind to receptor targets than to drugs that exert pharmacodynamic effects by inhibiting enzymes. For example, traditional monoamine oxidase inhibitors (MAOIs) irreversibly inhibit monoamine oxidase, which in turn cannot regenerate for at least 2 weeks--even though the half-life of drugs such as tranylcypromine or isocarboxazid is relatively short (see appendix to this chapter). Drugs or compounds that inhibit CYP enzymes rapidly and irreversibly shut down the enzyme (e.g., grapefruit juice and CYP3A4), which then may take from 1 to 3 days to regenerate. Third, half-lives refer to steady-state pharmacokinetics in the bloodstream but may not necessarily be particularly informative about the bioavailability of a drug at its end-organ site(s) of action. For example, lithium (as a lipophilic ionophore) can remain in brain and bone tissue long after serum levels become zero (as often occurs following a toxic overdose). The selective serotonin reuptake inhibitor (SSRI) fluvoxamine also has been shown by magnetic resonance spectroscopy to have a brain elimination half-life of 58 hours but a plasma elimination half-life of about half that (26 hours) (Strauss *et al.* 1998).

Drugs with a relatively short half-life do not necessarily require multiple daily doses. For example, risperidone has a fairly short half-life of about 3 hours, but its active metabolite 9-hydroxy-risperidone (i.e., paliperidone) has a half-life of about 30 hours. Nefazodone follows nonlinear (first-order) pharmacokinetics (defined in the next section); its pharmacokinetics (C_{min} and AUC) appear similar with once-or twice-daily dosing (Marathe *et al.* 1996). Quetiapine, despite a terminal elimination half-life of around 6 hours, has been studied and used successfully with once-daily (nighttime) dosing for bipolar depression to minimize daytime sedation (e.g., Calabrese *et al.* 2005).

The concept of drug "clearance" is really an amalgam of the processes of metabolism and elimination. The clearance rate of a drug follows different mechanics depending on the extent to which saturation or nonsaturation of a (catabolic) enzyme affects the breakdown of its substrate. Three kinds of elimination kinetics have been described.

Zero-order elimination kinetics means that metabolism *becomes saturable* in excess and a *constant amount* of drug is eliminated per unit time, regardless of the plasma concentration. In other words, the rate of reaction depends solely on time and not drug concentration, as depicted in Figure 6-1A, and plasma concentration declines proportionally with time as shown in Figure 6-1B. Few drugs follow zero-order kinetics. Pertinent examples include ethanol, methanol, fluoxetine, and phenytoin. Such drugs will build up higher concentrations over time as compared to those that follow first-order kinetics.

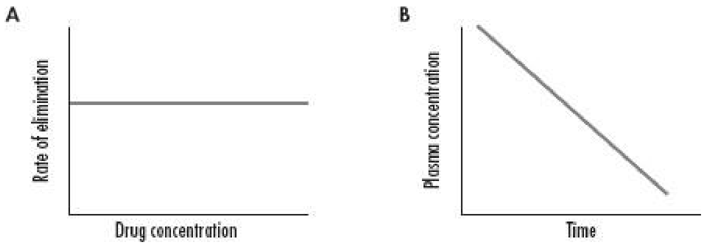

FIGURE 6-1. Zero-order elimination kinetics.

(A) Rate of reaction depends solely on time and not drug concentration. **(B)** Plasma concentration declines proportionally with time.

The majority of psychiatric drugs are eliminated by *first-order kinetics*. In first-order kinetics, a *constant proportion* of drug is eliminated per unit time, and the process is entirely dependent on drug concentration (i.e., drugs at higher concentration are eliminated faster than drugs at lower concentration) and driven mainly by diffusion. Drug elimination in first-order kinetics follows an exponential decay curve, as shown in Figure 6-2A. Plotted on a logarithmic scale, the relationship between drug concentration and elimination rate is depicted in Figure 6-2B. Elimination increases proportionally as drug concentration increases. First-order elimination kinetics is thus considered a linear process because the rate of elimination is proportional to the drug concentration (i.e., the elimination process cannot become saturated).

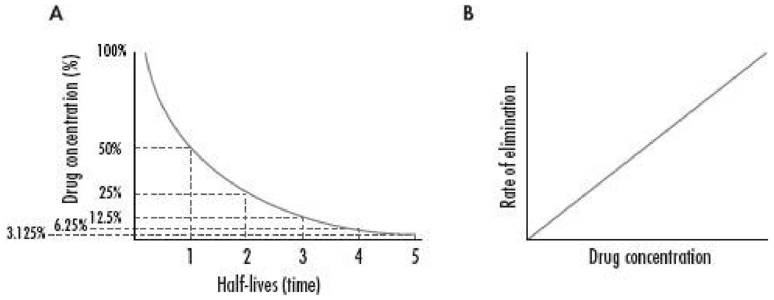

FIGURE 6-2. First-order elimination kinetics.

(A) Exponential decay across five elimination half-lives of a drug that follows first-order elimination kinetics. **(B)** First-order elimination kinetics plotted as a logarithmic function.

Nonlinear kinetics occurs if the availability of a metabolic enzyme becomes saturated, such that further increases in drug concentration no longer cause increased elimination (as is the case in first-order kinetics). Thus, *second-order elimination* involves a logarithmic growth curve when plotting the rate of enzymatic reaction (y-axis) by drug dose, as depicted in Figure 6-3A. When elimination is expressed as the relationship between steady-state drug concentrations (y-axis) and further dose increases (x-axis) (Figure 6-3B), we can see that in the setting of high drug concentrations, even minor drug dosage changes will cause substantial further increases in drug concentration. The graph shown in Figure 6-3A depicting logarithmic second-order elimination kinetics also reflects the saturation curve described by the Michaelis-Menten equation, explaining how the rate of an enzymatic reaction increases as the substrate concentration increases:

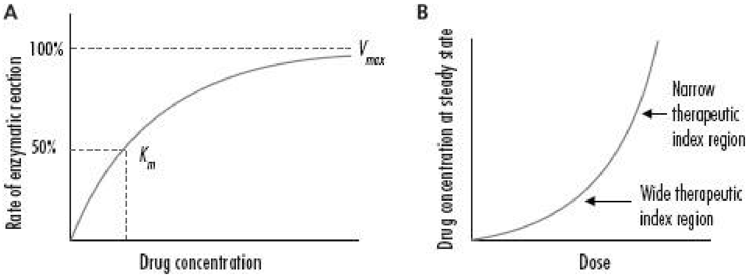

FIGURE 6-3. Second-order elimination kinetics.

(A) Logarithmic growth curve obtained by plotting the rate of enzymatic reaction (y-axis) by the drug concentration (x-axis). **(B)** Second-order elimination expressed as the relationship between steady-state drug concentrations (y-axis) and further dosage increases (x-axis). K_m = drug concentration at 50% of V_{max}; V_{max} = maximal rate of reaction.

$$V = \frac{V_{max} \times [S]}{K_m + [S]},$$

where V equals the velocity or rate of a reaction, V_{max} represents the maximum rate of the reaction, $[S]$ represents the substrate (drug) concentration, and K_m indicates the substrate concentration at 50% of V_{max}.

A further practical implication of drugs that follow second-order elimination kinetics involves therapeutic indices. Medications with concentration ranges toward the less steep left-hand side of the curve in Figure 6-3B tend to have broader therapeutic indices (i.e., small changes in dosage will not so drastically affect serum levels),

whereas concentrations toward the steeper right-hand side of the curve have narrower therapeutic indices. Correspondingly, incremental dosage increases may be more likely to lead to toxicity states. Drugs that must achieve 50% of V_{max} (i.e., K_m) to exert a meaningful pharmacodynamic effect are often considered to have a narrow therapeutic index. Psychotropically relevant examples of drugs with narrow therapeutic indices are lithium carbonate, carbamazepine, and levothyroxine.

Dose-Response Relationships

Dose-response curves are graphical depictions of the relationship of the magnitude of biological activity or pharmacodynamic effect of a drug (plotted on the y-axis) relative to increasing doses. When plotted as a logarithmic function, drug dose-response curves are often sigmoidal, as depicted in Figure 6-4.

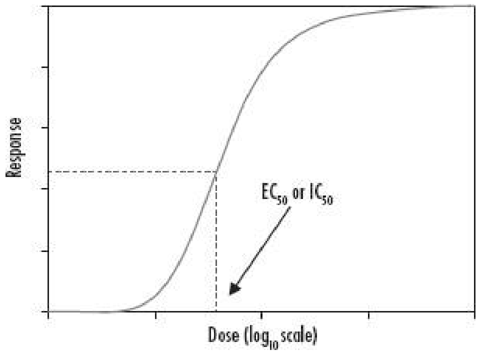

FIGURE 6-4. Sigmoidal drug dose-response curve.

EC_{50} = half-maximal effective concentration; IC_{50} = half-maximal inhibitory concentration.

The *half-maximal effective concentration* (EC_{50}) of a drug is sometimes taken as an indicator of potency, referring to the plasma concentration of a drug needed to obtain 50% of a maximal pharmacodynamic effect. EC_{50} is defined by the inflection point in the sigmoidal curve shown in Figure 6-4. Analogously, the *half-maximal inhibitory concentration* (IC_{50}) refers to the dose or concentration of a drug needed to inhibit half of the maximal response to an agonist.

Extended-Release Drug Formulations

Extended-release formulations of compounds do not necessarily alter the elimination half-life of a drug but may alter bioavailability because of differences in the delivery system between formulations. For example, divalproex ER produces about an 8%-20% lower serum valproic acid level than occurs with the conventional (delayed-release) formulation of divalproex (Sommerville *et al.* 2003)--meaning that the extended-release formulation is often dosed 20% higher than the delayed-release formulation to achieve bioequivalence. The extended-release formulation of quetiapine (quetiapine XR) has the same half-life as immediate-release (IR) quetiapine (about 6 hours), but the IR formulation has a considerably higher C_{max} and faster time to peak plasma concentration (T_{max}), which could have implications for the time course and magnitude of adverse effects such as sedation.

Extended-release compounds may have the pharmacokinetic advantage of minimizing excursions from maximal to minimal blood levels (C_{max} and C_{min}, respectively), and it is often at least theoretically possible that nighttime dosing can sometimes minimize the impact of possible adverse effects (such as sedation with antihistaminergic drugs) when C_{max} occurs during sleep. Notably, extended-release formulations of a drug generally do not alter a drug's terminal elimination half-life; rather, they involve enteric coatings, osmotic pumps, or other release systems that slow the release of a drug from the gastrointestinal to the circulatory system. Maximal peak and trough concentrations of an extended-release drug are thereby achieved based more on absorption than on elimination.

Extended-release formulations tend to be absorbed more distally in the gastrointestinal tract and consequently provide less reliable forms of drug delivery in patients who have undergone bariatric surgery, including restrictive procedures (i.e., gastric sleeve or banding) or both restrictive and malabsorptive procedures (i.e., gastric bypass, or Roux-en-Y procedure). Bariatric surgery can impair gastric motility, decrease gastric volume, raise gastric pH (potentially decreasing the solubility of basic drugs and increasing the solubility of acidic drugs), and decrease surface area for gastric absorption. After gastric bypass, first-pass metabolism of CYP3A4 substrates may decrease, and less contact with biliary secretions and carrier proteins (e.g., P-glycoprotein) can alter absorption and elimination, potentially necessitating lower drug dosages to achieve desired effects.

Orally disintegrating forms of a drug generally have the same half-life and bioavailability as non-orally disintegrating formulations. Drugs with long terminal elimination half-lives (i.e., > 24 hours) generally can be dosed once daily with little concern about reliable pharmacodynamic efficacy; however, tolerability may sometimes require oral administration in divided doses to minimize adverse effects (e.g., gastrointestinal or neurological adverse effects from high-dose lithium or divalproex--either of which can in principle be taken once daily).

Examples of key pharmacokinetic parameters for commonly used psychotropic drugs are summarized in the tables presented in the appendix to this chapter.

Phases of Drug Metabolism

Hepatic drug metabolism is divided into two phases. *Phase I* involves conversion of a drug to more polar (water-soluble) molecules via oxidation (e.g., hydroxylation, dealkylation, deamination), reduction, and hydrolysis reactions, mediated primarily by CYP isoenzymes. *Phase II* metabolism involves conjugation of drug or phase I metabolites with other molecules, as occurs during glucuronidation (e.g., via uridine diphosphate [UDP]-glucuronosyltransferase), acetylation (e.g., via *N*-acetyltransferase), methylation (e.g., via methyltransferase), sulfonation (e.g., via sulfotransferase), glutathione conjugation (e.g., via glutathione-*S*-transferase), and amino acid conjugation (e.g., via aminoacyl-transfer RNA [tRNA] synthetases). "Slow acetylator" genotypes (seen among 40%-70% of white and Black individuals, 10%-20% of Japanese and Canadian Eskimos, and 80% of Egyptians) lead to inefficient acetylation of drug substrates for *N*-acetyltransferase, potentially causing higher-than-usual blood levels and adverse effects; among psychotropic compounds, phenelzine is perhaps the most commonly observed drug that is appreciably metabolized by acetylation.

As discussed in a later section of this chapter, genetic variants in CYP enzymes, and at least some phase II enzymes, can influence the rate and extent of catabolism for their substrate drugs and are a foundation for understanding the pharmacogenetic influence on pharmacokinetics.

Therapeutic Drug Monitoring: When Is It Useful?

Measurement of serum drug levels for a parent compound (say, fluoxetine or clozapine) and sometimes its active metabolite(s) (say, norfluoxetine or norclozapine, respectively) varies in its practical usefulness. Some compounds have well-established therapeutic reference ranges that inform prescribers about optimal dosing (e.g., nortriptyline, for which therapeutic response based on blood levels follows a bell-shaped curve) and the likelihood of "diminishing returns" (i.e., more adverse effects without more efficacy) with dosing beyond an upper threshold. Other agents might have narrow therapeutic indices (see Figure 6-3B), meaning that a laboratory reference range for blood levels not only corresponds to efficacy or "diminishing returns" but in fact encroaches on more hazardous toxicity beyond an upper limit (lithium represents probably the best example here). Elsewhere, there are compounds for which "therapeutic" reference ranges have been established for pharmacodynamic efficacy unrelated to psychotropic properties--notably, in the case of anticonvulsants such as carbamazepine or lamotrigine, where serum levels are more informative about likelihood of adequate seizure prophylaxis, but not necessarily mood-stabilizing properties. Or, a drug may have an established therapeutic reference range for blood levels that pertains only to a particular phase of illness (as in the case of serum valproic acid levels for acute mania, but not for acute bipolar depression or for relapse prevention). In empirical studies, plasma levels for certain compounds, such as fluoxetine and its active metabolite, norfluoxetine, have been shown *not* to correlate with relapse after initial response (Brunswick *et al.* 2002), perhaps in part because fluoxetine displays zero-order rather than first-order kinetics.

Therapeutic drug monitoring can be useful in the following contexts:

Tracking adherence. It is simple enough to measure a serum level of almost any drug merely for the sake of affirming that the compound is present in the body. Such "affirmation" may vary considerably based on the half-life of a given drug, meaning that haphazard adherence to a regimen will be detected with less sensitivity in a compound with a long half-life (e.g., aripiprazole or cariprazine) than in a compound with a short one (e.g., ziprasidone).

Monitoring for toxicity. Particularly in the case of drugs with narrow therapeutic indices, laboratory plasma reference ranges can affirm when observed adverse effects may indicate toxicity (e.g., tremor with lithium or divalproex; ataxia with carbamazepine).

Monitoring for pharmacodynamic efficacy. Therapeutic reference ranges for plasma drug concentrations have been established and validated for some, but not all, psychotropic compounds. Examples include most tricyclic antidepressants, lithium during the acute and maintenance phases of treatment for bipolar disorder, clozapine in schizophrenia, and divalproex for acute bipolar mania. A more provisional literature supports the use of tracking serum levels of O-desmethylvenlafaxine for predicting response to venlafaxine (e.g., Stamm *et al.* 2014) or duloxetine serum levels for predicting duloxetine antidepressant response (e.g., De Donatis *et al.* 2019). Among antipsychotics, serum clozapine levels above 350 ng/mL have been associated with more robust efficacy in schizophrenia (VanderZwaag *et al.* 1996), with more provisional and preliminary findings reported with a handful of other second-generation antipsychotics (notably, olanzapine, risperidone, and aripiprazole [reviewed in Goldberg and Stahl 2021]). High interindividual variability in serum drug concentrations relative to dosing has posed a limitation for drawing generalizable inferences about drug levels and pharmacodynamic response for many compounds.

Gauging room for improvement. Available therapeutic plasma concentration ranges can help to guide or inform optimal dosing because they provide general estimates about the likelihood of achieving and sustaining a therapeutic effect based on population studies. As such, however, they may not necessarily translate to every individual; a clinically stable patient with a technically subtherapeutic nortriptyline or lithium blood level may not necessarily benefit from higher dosing simply to achieve a higher plasma level in the absence of symptoms (they might, however, incur more adverse effects). At the same time, measuring a serum drug level in a patient who remains clinically symptomatic can help establish room for upward dosing with expected tolerability.

Monitoring pharmacokinetics in special situations. In the clinical settings of malnutrition, hypoalbuminemia, and malabsorption syndromes, measuring the free/unbound fraction of protein-bound drugs (e.g., valproate) may yield information about possible impaired absorption or distribution, as noted above in Clinical Vignette 1. In pregnancy, lamotrigine levels may decline substantially throughout all trimesters as a result of estradiol upregulation of *UGT1A4* gene expression and increased clearance of lamotrigine by as much as 175%--thus constituting one of the rare instances in which serum lamotrigine levels are viewed by some authors as having clinical relevance in psychiatry (Clark *et al.* 2013). See Clinical Vignette 2 below for a more detailed illustration of lamotrigine dosing management during pregnancy.

Assessing pharmacokinetic interactions. Monitoring of serum drug levels can be useful (and often necessary for safety purposes) when drugs that inhibit or induce metabolic enzymes are being coprescribed. Examples would include following tricyclic antidepressant levels when coprescribing SSRIs that inhibit CYP2D6.

Clinical Vignette 2

A 28-year-old woman with bipolar disorder, most recent episode depressed and in remission, was stably maintained for over 1 year on lamotrigine 200 mg/day with quetiapine 300 mg/day. Her stated plan to become pregnant prompted a clinical review affirming the benefits and relative safety of her current regimen during pregnancy. A decision was made to measure a baseline (reference) serum lamotrigine level preconception, which was 4.2 mg/mL (laboratory reference range: 2.5-15 mg/mL). She conceived within 6 months. Some authors advocate measuring serum lamotrigine levels every 4 weeks during pregnancy, with automatic dosage increases by 20%-25% if a monthly serum level falls below the reference concentration (Sabers 2012), although others question the necessity of this as a routine practice because reductions in serum lamotrigine levels do not necessarily translate to increased symptoms (Sharma and Sommerdyk 2014). The patient was followed clinically by her psychiatrist on a monthly basis and weekly by her nonmedical psychotherapist. Around week 26 of her pregnancy she reported increased low-grade depressive symptoms, and a serum lamotrigine level measured at that time was 1.3 mg/mL. Dosing was increased to 250 mg/day, with improvement in depressive symptoms throughout the remainder of the pregnancy. A serum lamotrigine level measured 3 weeks postpartum was 5.1 mg/mL. Although that level was 21% higher than her reference concentration, the modestly higher dose was continued because it was well tolerated and she was euthymic.

When should serum drug levels be measured? Random levels may inform about the sheer presence or absence of a drug in the bloodstream but tell us little about therapeutic ranges or optimal dosing and consequently should not form the basis for decisions about optimized dosing. True trough serum levels of any drug are those measured *just before a next dose occurs* (regardless of the half-life of the molecule) (i.e., corresponding to C_{min}). In patients taking divalproex ER, serum valproate levels are ideally measured *no sooner* than 18 hours after the last dose in order to provide an estimate that is within 13% of the true trough value (Reed and Dutta 2006). The International Society of Bipolar Disorders/International Study Group on Lithium advises measuring a serum lithium level 12 +- 1 hours after a last ingestion in patients for whom lithium is dosed either once or twice daily (Nolen *et al.* 2019). Measurement of the 12-hour serum lithium level in patients who are using once-daily dosing may overestimate the true trough level, prompting some authors to advise multiplying the 12-hour level by 1.3 to better reflect the likely true trough and avoid underdosing (Reddy and Reddy 2014). Meaningful serum levels in general also are most interpretable when obtained no sooner than the passage of five elimination half-lives, in order to gauge steady-state kinetics.

Estrogens and progestins are metabolized by CYP3A4 and, as such, are subject to enzyme induction by several anticonvulsant drugs that induce 3A4. Table 6-1 summarizes clinically relevant known interactions between estrogen (either when formulated in oral contraceptives, as hormone replacement therapy, or during pregnancy) and anticonvulsants with known psychotropic effects.

TABLE 6-1. Pharmacokinetic effects of anticonvulsants on estrogen

Agent	Pharmacokinetic effect
Carbamazepine	Carbamazepine significantly reduces levels of estradiol.
Divalproex	Divalproex may reduce efficacy of estrogen-containing oral contraceptives.
Gabapentin	None
Lamotrigine	Estrogen (17-b-estradiol) upregulates uridine diphosphate (UDP)-glucuronosyltransferase (UGT) 1A4 2.3-fold, thereby increasing the metabolism of lamotrigine by about 50%; lamotrigine does not affect oral contraceptive levels.
Oxcarbazepine	Oxcarbazepine can decrease plasma concentrations of ethinylestradiol or levonorgestrel, potentially reducing contraceptive effectiveness.
Pregabalin	None
Topiramate	Topiramate increases estrogen metabolism.

Let us now turn more explicitly to a discussion of pharmacodynamics, beginning with the basis for drug efficacy (and tolerability) according to our understanding of drug/receptor target interactions.

Pharmacological Rationales: Do Drug Mechanisms of Action Matter?

Our knowledge of drug mechanisms of action remains rudimentary and largely inferential from preclinical studies examining suspected neurocircuits that underlie manifestations of psychopathology. While the field has long since moved past oversimplified explanations about monoaminergic "chemical imbalances" to explain mood disorders, or simplistic theories that schizophrenia results from "too much" or "too little" dopamine in the brain, the precision with which we can craft better drug interventions for serious mental disorders--or personalize treatments based on neurobiological parameters of any one individual patient--remains elusive. The field has come to think of dysregulated circuits, or neural networks, rather than neurotransmitters themselves, as more central to understanding psychopathology. Intended treatment targets focus more on downregulating or upregulating (or "tweaking" or fine-tuning) circuitry.

Receptor Binding Affinities and Ligand Dissociation

Drugs typically exert their pharmacodynamic effects by interacting either with receptors (such as inhibiting a transporter) or a catabolic enzyme (e.g., monoamine oxidase) to prevent neurotransmitter degradation. Ligand-receptor interactions are categorized based on agonist, antagonist, or partial agonist effects. Ligands engage their receptor targets with binding affinities that are measured as dissociation constants (K_d's)--a type of equilibrium constant--expressed in nanomoles (nM). Note that the terms K_i and K_d both represent measures of binding affinity between a ligand and a receptor. K_d denotes the dissociation constant for any ligand-receptor complex, whereas K_i refers more specifically to an enzyme-inhibitor complex. In general, drugs with low K_d's (i.e., low dissociation, meaning high affinity) exert potent pharmacodynamic effects at a given receptor, with consequent reflection in their perceived mechanism of action. Drugs with high binding affinities at specific receptors are often viewed as potent candidates for pharmacodynamic effects associated with that receptor, whether desired or undesired. For example, potent antagonism at a_1 receptors is thought to drive orthostatic hypotension (as seen with trazodone, prazosin, and second-generation antipsychotics such as risperidone or quetiapine).

Ligands with low K_d's are considered "tight" binders, whereas those with higher K_d's bind more loosely. Thus, antipsychotics with low K_d's at the D_2 receptor may predispose to a higher likelihood of adverse extrapyramidal effects, including acute dystonic reactions. In the early 2000s, Kapur and Seeman (2001) proposed the hypothesis that the pharmacodynamic "atypicality" of second-generation antipsychotics came from rapid dissociation from their D_2 receptor binding targets (eventually known as the "fast onset/fast offset" hypothesis). In this model, "loose" D_2 binding from agents with high K_d's presents an attractive strategy to minimize adverse dopalytic effects in the dorsal striatum and tuberoinfundibular pathways while preserving intact efficacy in mesocortical and mesolimbic tracts. Later authors have suggested that drug accumulation in the lipophilic cell interior might underestimate the speed of dissociation from D_2 receptors (Sahlholm *et al.* 2016).

Antihistaminergic drugs such as cyproheptadine (K_d = 0.06 nM), hydroxyzine (K_d = 2.0-19 nM), quetiapine (K_d = 2.2-11 nM), and diphenhydramine (K_d = 9.6-16 nM) are thought to exert marked sedating effects by virtue of their tight binding affinities at the H_1 receptor.

The following terminology describes the nature of ligand-receptor interactions:

Agonist: An agonist is a ligand that binds to a receptor and produces an activating response similar to that produced by an endogenous compound (e.g., a neurotransmitter).

Antagonist: An antagonist is a ligand that binds to a receptor and prevents its activation. Antagonists can be either *competitive* (i.e., they bind at the same active site as an endogenous ligand) or *noncompetitive* (i.e., they either bind irreversibly to the active site, or they bind to an allosteric modulatory site on the receptor). Naloxone is an example of a competitive antagonist at the mu opioid receptor, which reverses the activity of an agonist (e.g., morphine).

Partial agonist: A partial agonist binds to a receptor at its active site (which is also called an *orthosteric site*) but produces only partial efficacy relative to a full agonist, with a response as depicted in Figure 6-5. An example is buprenorphine (a partial agonist at the mu opiate receptor and an antagonist at the kappa opiate receptor).

Inverse agonist: A drug that binds to the same receptor as an agonist but produces the opposite pharmacodynamic effect (tantamount to an antagonist). However, inverse agonists require that the receptor they bind to has *constitutive activity*. That means that the receptor maintains a basal level of activity even in the absence of ligand binding. Inverse agonists block the constitutive activity of agonists. Examples include flumazenil (which binds to the benzodiazepine site of the $GABA_A$ receptor) and the antipsychotic pimavanserin (which is an inverse agonist of the 5-hydroxytryptamine type 2A ($5\text{-}HT_{2A}$) receptor and is used in the treatment of Parkinson's disease psychosis). Naloxone, as noted above, is a competitive mu opioid receptor antagonist (used to prevent overdose from buprenorphine) but also can function as an inverse agonist.

Neutral antagonist: Also known as *silent antagonists*, neutral antagonists are ligands that bind to a receptor but exert no intrinsic activity or change in signaling response, although they can block the activity of a full or partial agonist or inverse agonist.

Allosteric modulators: Some ligand receptors have so-called allosteric modulatory sites, which are locations on a receptor that are physically different from the location where an endogenous ligand (e.g., a neurotransmitter) binds, and which lead to upregulation or downregulation of receptor activity. These sites contrast with *orthosteric* or *ion channel sites*, which are the primary unmodulated ligand binding site on a receptor. Allosteric modulatory sites are in themselves inactive but when bound change conformation in order to become pharmacologically active or inactive. Examples include the *N*-methyl-D-aspartate (NMDA) ionotropic glutamate receptor, which has *glycine* and *glutamate* regulatory (allosteric modulatory) binding sites, as depicted in Figure 6-6.

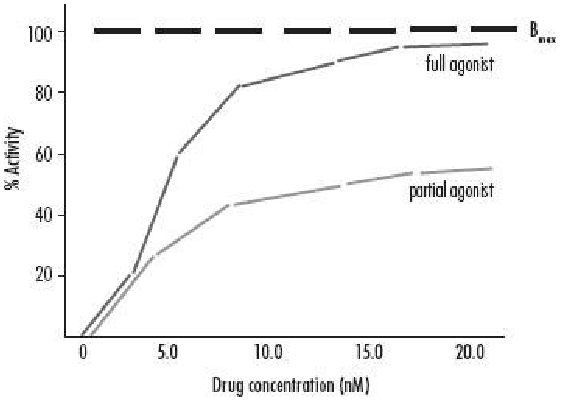

FIGURE 6-5. Dose-response curve for full and partial agonists.

B_{max} = maximal amount of bound drug; nM = nanomolar.

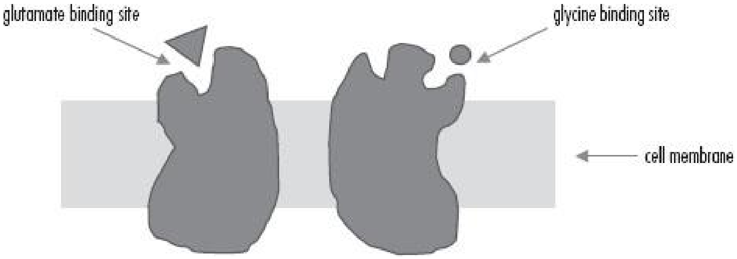

FIGURE 6-6. Allosteric binding sites on the *N*-methyl-D-aspartate (NMDA) receptor.

It was noted earlier in this chapter that we no longer think of psychopathology as resulting from "chemical imbalances" so much as dysregulation of neural circuitry, and modulation of neurotransmission along particular circuits or networks is thought to fine-tune signaling. We can now go one step further and speak of the specific receptor targets of neurotransmission in ways that might help to predict both drug efficacy and tolerability. Consider serotonergic circuitry as an example. An SSRI effectively increases the availability of serotonin quanta by blocking presynaptic reuptake. Imagine

a ship leaving its dock but then, upon return from its brief voyage, discovering that the dock (the serotonin transporter protein) is closed and that it must remain at sea longer than would otherwise be the case. Enhanced availability of serotonin quanta across the synapse could lead to indiscriminately enhanced postsynaptic binding, resulting in more "collateral damage" than one might hope for. "Indiscriminate" or undesired binding at some postsynaptic targets creates adverse effects; thus, agonism at the postsynaptic 5-HT_3 receptor causes nausea (perhaps the most common adverse effect across SSRIs); agonism at 5-HT_{2A} receptors can cause sexual dysfunction; agonism at 5-HT_7 receptors enhances GABA-mediated inhibition of serotonin release in the raphe nucleus; and antagonism at 5-HT_{2C} receptors can cause appetite increases and weight gain. A "smart" serotonergic drug would selectively agonize (activate) postsynaptic 5-HT_{1A} receptors (for a putative antidepressant and anxiolytic effect) while selectively blocking 5-HT_{2A}, 5-HT_3, and 5-HT_7 receptors and agonizing (activating) 5-HT_{2C} receptors.

Tachyphylaxis and Tolerance

True *tachyphylaxis* involves a rapidly diminishing pharmacodynamic response to repeated doses of a drug over a relatively short period of time. This response is a non-dose-dependent, rate-sensitive phenomenon that often resolves after a hiatus from drug administration. Common examples of drugs known to produce tachyphylaxis are psychedelics, opioids, and nicotine. (A frequent clinical dilemma involves differentiating tachyphylaxis from the progressive worsening of the natural course of an illness, for which a once-efficacious drug dosing regimen may simply become inadequate to overcome increasing severity of the underlying disease process.) *Tolerance*, by contrast, refers to the more gradual need for larger doses of a drug to achieve the same effect as previously established during long-term administration. It involves increased drug clearance and is believed to reflect downregulation of receptor number, function, or sensitivity. Chronic ethanol exposure would exemplify tolerance, in which CYP enzyme induction leads to accelerated clearance and the need for increasing doses to achieve a previously observed pharmacodynamic effect. The concept of *cross-tolerance* means than different drugs with similar receptor targets can be substituted for one another, as occurs when using benzodiazepines to detoxify patients from alcohol, or substituting one opiate for another (e.g., methadone for heroin) to avoid withdrawal.

In the case of tolerance that develops to MAOIs, serotonergic antidepressants, or psychostimulants, dosage increases often will at least temporarily overcome diminished efficacy (as limited by higher-dose potential safety considerations) and will be less disruptive than undertaking a drug holiday followed by rechallenge at usual starting doses. The absence of randomized trials examining tolerance to psychotropic drugs limits the evidence base from which to identify optimal management.

Drug Stereoisomers

Racemic versus enantiomeric formulations of psychotropic drugs can vary in their pharmacokinetics and pharmacodynamics. Levorotatory (left-handed) and dextrorotatory (right-handed) enantiomers of chiral molecules also can differ in drug potency. For example, dextroamphetamine has a shorter half-life and higher potency than levoamphetamine--making mixed amphetamine salts a less potent racemic formulation than the pure dextro molecule. Similarly, the *S*-enantiomer of ketamine is about three to four times more potent than racemic ketamine, but the intravenous mode of administration for racemic ketamine has higher bioavailability (by definition, 100%) than intranasal esketamine (about 50%). Enantiomeric armodafinil has a duration of effect that lasts about 2 hours longer than that of racemic modafinil. Levomilnacipran has a somewhat longer half-life (12 hours) and higher antidepressant potency than racemic milnacipran (8 hours). A pooled analysis comparing enantiomeric escitalopram versus racemic citalopram for MDD found a significantly greater reduction in depression severity scores and a higher response rate (56% vs. 41%) with the former than with the latter (Azorin *et al.* 2004).

Pharmacogenomics and Pharmacogenetics

The field of clinical therapeutics has increasingly moved toward the concepts of personalized medicine (i.e., customized treatment) and precision medicine (i.e., using genetic and molecular profiling) (see Chapter 8, "Personalized Medicine in Psychiatry," and Chapter 9, "Machine Learning in Psychopharmacology," in this textbook), inspired largely by interest in applying findings from the human genome project to devising treatments (mainly in oncology and infectious diseases) tailored to the genetic specifications of a single individual. There remains great debate about the commercial applicability of pharmacogenetics to psychiatry, where many factors other than genetics likely contribute to treatment outcomes, and most study findings thus far have been provisional and await replication. This section will address practical knowledge and implications of pharmacogenetic testing with respect to relevance for clinical practitioners.

Although the terms *pharmacogenetics* and *pharmacogenomics* are often used interchangeably, the former technically refers to single-gene variations that are thought to influence drug response, while the latter refers more broadly to the collective influence on drug effects of genetic variability across the entire genome. From among the roughly 20,000 genes in the human genome, those that code for functional proteins can have alterations in their nucleotide sequences that produce functional variants (called *single nucleotide polymorphisms*, or SNPs). Functional SNPs represent candidate genes that may be associated with proteins involved in drug metabolism or pharmacodynamic efficacy. Two main foci of interest have driven most pharmacogenetic investigations in psychiatry: 1) the identification of allelic variants in genes that code for catabolic enzymes involved in phase I or phase II metabolism (for which pharmacokinetic effects can influence delayed or hastened elimination, tolerability and adverse effects, and conversion of parent drugs to active metabolites) and 2) SNPs involved in candidate genes whose products exert specific pharmacodynamic effects, such as receptor targets or intermediary products in key biochemical (e.g., monoaminergic) pathways.

One of the key limitations in pharmacogenetic studies involves the fact that psychiatric genetics is almost always non-Mendelian, meaning that multiple genes of small effect are the contributors to observed phenotypes that represent complex traits. That in turn means that enormous statistical power is generally needed to identify the very small effects expected from genetic influences. Furthermore, the field has increasingly turned away from the concept of investigating single candidate genes and their potential associations with drug effects and instead endeavored to focus on genome-wide association studies (GWAS) for the sake of obtaining valid and replicable findings. Adequate sample sizes to provide sufficient power for GWAS (where *P* values generally must be less than 5 x $10^{[?]8}$) have not, as yet, been undertaken in any combinatorial pharmacogenetic studies in psychiatry.

Epigenetic Modifications

Epigenetic modifications refer to stable, reversible, heritable alterations in gene expression that occur without changes to an original DNA sequence. Posttranscriptional

modifications that can occur to DNA in response to psychotropic drug exposure constitute epigenetic events that can alter DNA accessibility or chromatin structure. The most prominent examples among these are DNA methylation or histone acetylation/deacetylation, as well as phosphorylation, deimination, ubiquitylation, SUMOylation (i.e., addition of small ubiquitin-related modifiers [SUMOs]), and adenosine diphosphate (ADP) ribosylation. The addition of methyl groups to cytosine residues of DNA (generally, cytosine-phosphate-guanine (CpG) dinucleotides, or CpG sites, often found in DNA promoter regions) *suppresses* gene expression by silencing genes and blocking the binding of transcription factors to promoter regions. Notably, animal models of depression identify increased methylation of brain-derived neurotrophic factor (BDNF), leading to reduced transcription and translation (Webb *et al.* 2020) that is, at least in principle, reversible by demethylation. In preclinical in vitro studies, astrocyte exposure to amitriptyline has been shown to produce DNA hypomethylation (Perisic *et al.* 2010). The SSRI escitalopram has been shown to reverse hypermethylation at a gene called *P11* (known also as the S100 calcium-binding protein A10 gene, or *S100A10*, a putative risk allele for depression) (Melas *et al.* 2012). However, studies of the effects of antidepressants more broadly on DNA methylation versus demethylation have also produced counterintuitive findings, with some reports identifying *hyper*methylation after antidepressant exposure at the BDNF promoter, and others reporting links between *hypo*methylation of monoamine oxidase A (MAO-A) and a *poorer* response to antidepressants. Methylation of sites within a number of candidate genes in addition to *BDNF*, including *SLC6A4*, *HTR1A*, *HTR1B*, *IL11*, and the whole genome, have been reported in association with antidepressant response (Webb *et al.* 2020). It remains uncertain whether such findings regarding methylation (versus demethylation) and antidepressant response represent truly conflicting results versus possible type I errors, or simply raise questions about the true role of suspected candidate genes, such as *BDNF*, and their regulation in MDD.

Histone acetylation refers to the addition of acetyl groups to lysine residues located on histones (basic proteins around which DNA is wound); acetylation allows greater interaction of DNA binding proteins with exposed chromatin strands, in turn upregulating gene transcription. Histone deacetylase inhibitors may represent an attractive strategy for understanding psychotropic drug effects at the molecular level. Divalproex, for example, has been shown to inhibit histone deacetylase (Phiel *et al.* 2001) among its varied known mechanisms of action.

Let us now consider more specifically the clinical relevance of pharmacogenetics separately with respect to pharmacokinetic versus pharmacodynamic aspects of psychopharmacology. It is worth first noting that despite enthusiasm from many commercial vendors of pharmacogenetic testing kits, regulatory agencies have expressed caution about the utility of ordering pharmacogenetic testing in a routine fashion with the hopes of predicting psychotropic drug response. Indeed, on October 31, 2018, the FDA issued a consumer safety warning regarding pharmacogenetic test results with respect to antidepressants. The FDA noted that "the relationship between DNA variations and the effectiveness of antidepressant medication has never been established" and suggested that "healthcare providers should not make changes to a patient's medication regimen based on results from genetic tests that claim to predict a patient's response to specific medications" (U.S. Food and Drug Administration 2018). Similarly, the American Psychiatric Association Council of Research Task Force

on Novel Biomarkers and Treatments concluded in 2018 that "at present, there are insufficient data to support the widespread use of combinatorial pharmacogenetic testing in clinical practice" but did note that testing may sometimes be informative for predicting some adverse drug events

(Zeier *et al.* 2018). Readers are advised to adopt a critical perspective when interpreting the available literature on both safety and efficacy pharmacogenetics, considering the methodological limitations described below, before extrapolating findings to direct patient care.

Pharmacokinetic Pharmacogenetics

Recall from earlier discussions that phase I and phase II catabolic enzymes are responsible for modifying drug substrates that undergo metabolism either to biologically active metabolites or to products eliminated from the body. Known genetic variants that code for pharmacokinetic enzymes may contribute to the efficiency or inefficiency of drug metabolism by producing genotypes (metabolic enzymes) that are normal (called "extensive metabolizers," or EMs), overactive (called "ultrarapid metabolizers," or URMs), or inefficiently slow (called "poor metabolizers," or PMs). Drugs that are substrates for phase I or phase II enzymes in URM or PM genotype patients may have impaired responses due to hastened metabolism or delayed drug clearance (and consequent greater side-effect burden), respectively. While commercially available pharmacogenetic testing protocols tend to advise the all-or-none avoidance of drugs that are metabolized by specific catabolic enzymes in PMs or URMs, another clinical approach would be to anticipate the need for lower-than-usual dosing of a drug that is a substrate for an enzyme with the PM genotype, or to consider ostensibly supratherapeutic dosing of specific drugs metabolized by enzymes with URM genotypes. More absolute contraindications to using a drug in a PM genotype patient would be those for which conversion from a prodrug to an active metabolite is precluded, as in the case of conversion of tamoxifen to endoxifen via CYP2D6 (i.e., for the same reasons that tamoxifen should not be coprescribed with potent 2D6 inhibitory drugs such as paroxetine, fluoxetine, and duloxetine, as listed in Table 6-2).

Notably, a relatively small proportion of the population has either URM or PM genotypes at loci for catabolic enzymes, and those proportions stratify across racial-ethnic groups. Pharmacogenetic studies therefore must account for possible racial-ethnic-geographic population stratification when reporting findings across subject groups. Known allele frequencies for URMs and PMs across several CYP isoenzymes involved in psychotropic drug metabolism, with examples of known drug inhibitors and inducers, are summarized in Table 6-2.

Several antidepressants (specifically, citalopram, escitalopram, venlafaxine, tertiary amine tricyclics) also are substrates for *P-glycoprotein*, a cell membrane protein encoded by the gene *ABCB1* that transports xenobiotics across the blood-brain barrier. Some studies have found that higher antidepressant doses may be needed to exert therapeutic effects in "G" allele carriers at the *ABCB1* 2677 G > T SNP, although conflicting findings have also been reported (Wolking *et al.* 2015).

With respect to pharmacogenetic variants of phase II metabolic enzymes, several examples are noteworthy. Valproic acid and lamotrigine are both metabolized via UDP-glucuronosyltransferase (UGT) glucuronidation. In the case of divalproex, several candidate genes have been preliminarily studied, including *UGT1A3*, *UGT1A4*, *UGT1A6*, *UGT1A8*, *UGT1A9*, *UGT1A10*, *UGT2B7*, and *UGT2B15* (Krishnaswamy *et al.* 2005). With respect to lamotrigine, variants of *UGT1A4* and *UGT2B7* have been studied in relation to drug concentration-to-dose ratios (CDRs). Known SNPs of *UGT1A4* (i.e., 70 C > A or 142 T > G) have not been shown to influence lamotrigine CDRs, but homozygotes for the *UGT2B7* -161 C > T polymorphism have been shown to produce higher lamotrigine CDRs than are seen among heterozygotes or wild types (Kim and Kim 2019).

Despite speculation that PMs would be expected to incur an overabundance of adverse drug effects, the empirical literature in this area, though sparse, has not been especially compelling. In MDD, one of the largest randomized trials conducted to date (the Genomics Used to Improve DEpression Decisions [GUIDED] study), found that, contrary to expectations, MDD patients randomly assigned to treatment informed by a combinatorial pharmacogenetics panel did not differ from MDD patients who received treatment as usual (TAU) in their mean number of antidepressant drug side effects (0.243 vs. 0.237, $P = 0.885$) or the proportion of subjects who experienced side effects (about 15% in both the pharmacogenetically guided arm and TAU)

(Greden *et al.* 2019). However, subjects whose medications were switched to pharmacogenetically congruent options subsequently had significantly fewer adverse effects as compared to those who did not.

On the other hand, certain adverse effects have been shown to demonstrate more compelling associations with specific genes or risk alleles. From among the examples listed in Table 6-3, perhaps the most well recognized is the association between the gene *HLA-B*1502* and the risk for developing Stevens-Johnson syndrome after exposure to carbamazepine in individuals of Southeast Asian descent. In fact, the manufacturer's product labeling for carbamazepine carries a boxed warning that requires assessment for the presence of this gene before prescribing carbamazepine to at-risk individuals. Another example of compelling data for the use of pharmacogenetic testing for safety purposes involves the recognition of CYP2D6 PMs for whom drugs may be prescribed that can cause QT prolongation on electrocardiogram. Iloperidone, for example, includes language in its manufacturer's product label stating that dosage "should be reduced in patients who are poor metabolizers of CYP2D6." The manufacturers' product labeling for most tricyclic antidepressants also includes language warning of the risk for higher drug plasma levels among patients with PM genotypes for CYP2D6.

Pharmacodynamic Pharmacogenetics

More uncertainty and debate revolve around the use of routine pharmacogenetic testing to predict psychotropic drug efficacy. Some aspects of drug efficacy become intuitively obvious when considering the pertinent metabolic pathways of particular drugs, especially those whose biological activity is dependent on conversion from a prodrug to an active compound or an active metabolite. For example, venlafaxine depends on CYP2D6 for conversion to its primary active metabolite, desvenlafaxine. This process will be anything but efficient in CYP2D6 PMs, effectively rendering venlafaxine an inactive compound in PMs because of the blockade in its metabolic pathway. Carbamazepine is essentially a prodrug that must be converted by CYP3A4 to carbamazepine-10,11-epoxide (which may not occur in CYP3A4 PMs). Risperidone must be converted to its primary active metabolite, 9-hydroxyrisperidone (otherwise known commercially as paliperidone), primarily via CYP2D6, although because CYP3A4/5 provides a secondary degradative pathway for risperidone, it is possible that a CYP2D6 PM might nevertheless spare *some* buildup of the parent compound. It is worth noting here the observation made by Macaluso and Preskorn (2018) that simply by avoiding antidepressants and antipsychotics that undergo oxidative metabolism, clinicians can most of the time replicate the same "binned" recommendations made by most pharmacogenetic testing protocols. One might add that pharmacokinetic candidate genes have little if any relevance for drugs that are metabolized by multiple metabolic pathways (see appendix to this chapter) or those that undergo no biotransformation before being eliminated.

Studies of combinatorial pharmacogenetics designed to predict symptom improvement, response, and remission have been conducted in mainly a preliminary fashion in MDD, schizophrenia, and a handful of other conditions such as ADHD, and for most existing provisional findings, the field lacks replication studies (much less those with adequate statistical power). Initial open, nonrandomized trials in MDD were criticized for failing to account for expectancy bias among pharmacogenetic recipients (meaning that patients and providers were both aware that a specialized type of treatment would be occurring). The aforementioned GUIDED trial--a blinded randomized trial--failed to show a significant advantage for pharmacogenetically informed care over TAU for MDD on the primary outcome (change in symptom reduction) (Greden *et al.* 2019). A series of post hoc analyses from that database showed a nominally significant advantage for pharmacogenetically guided care for achieving "response" (26% with pharmacogenetics vs. 19.9% with TAU) and "remission" (15.3% with pharmacogenetics vs. 10.1% with TAU), producing a small magnitude of effect (number needed to treat [NNT] = 17 for response and 19 for remission) (Goldberg *et al.* 2019).

There now exist a large number of candidate genes that have been studied for possible associations with pharmacodynamic efficacy, mostly in the case of antidepressant or antipsychotic response to pharmacotherapies in MDD and schizophrenia, respectively. Some are of mainly theoretical relevance to concepts such as neuroprotection (e.g., the *BDNF* Val^{66} polymorphism) or are linked with enzymes or intermediary products in the synthesis of monoaminergic neurotransmitters (e.g., *TPH2* [tryptophan hydroxylase] for production of serotonin); still others are candidate gene polymorphisms involved in protein synthesis for ion channels (e.g., *CACNA1C* and the calcium channel) or neurotransmitter receptors (e.g., *DRD4* variants and the dopamine D$_4$ receptor; *SLC6A4* variants and the serotonin transporter gene).

It is often a matter of speculation as to whether known polymorphisms of genes such as these meaningfully and reliably produce observable pharmacodynamic effects. For example, consider the degradation of dopamine via catechol-O-methyltransferase (COMT), for which a known polymorphism (Val^{158}Met, also known as rs4680) produces a high activity (Val/Val) and a low activity (Met/Met) variant. Low-activity variants, in principle, lead to less degradation of dopamine, which could have implications for attentional processing in disorders such as schizophrenia or ADHD. One commercial pharmacogenetics company directs prescribers to favor nonstimulant treatment options for ADHD in patients homozygous for Met/Met (low activity) rs4680, based on the hypothesis that a dopamine agonist may be less effective in such patients. Is this evidence-based? A meta-analysis examining methylphenidate response vis-a-vis COMT genotype identified seven studies (five of which had nonsignificant confidence intervals) that collectively revealed a statistically significant 40% increased chance of response in Val/Val homozygotes (Myer *et al.* 2018). How does this finding generalize to predict the utility of stimulants in children with ADHD, relative to other factors associated with treatment outcome, such as IQ, age, severity, or concurrent anxiety (Buitelaar *et al.* 1995)? Does it extrapolate to adults with ADHD? Does it pertain to use of amphetamine as well as methylphenidate? (A Medline search reveals no pharmacogenetics studies specifically examining the COMT polymorphism and amphetamine response but conflicting findings regarding neurocognitive performance among healthy adults given D-amphetamine, stratified by COMT genotype.) Perhaps most importantly, is there evidence of better response to nonstimulant treatments for ADHD (e.g., atomoxetine) in rs4680 Met/Met homozygotes? (A Medline search revealed no studies examining this question.) These are among the key unanswered questions that stand between the bench and the bedside in relation to translating pharmacogenetics into a "ready for prime time" commercial enterprise.

Similar unknowns and caveats bear on existing candidate gene studies in relation to predicting antidepressant response in MDD. From among the many dozens of candidate genes that have been studied in exploratory fashion relative to antidepressant response, several have received particular attention. Particular interest has coalesced around the potential association between antidepressant response and the presence of short (s) versus long (l) allelic variants of the serotonin transporter gene polymorphism (locus *SLC6A4*). Carriers of the long variant (and, in particular, the L_A subtype) produce more serotonin transporter protein than do carriers of the short variant, or those with the L_G long variant--a consequence that, at least in principle, could predispose to a better response to SSRIs. A meta-analysis of 16 SSRI trials found an overall 1.7-fold greater likelihood of SSRI antidepressant response among l/l homozygotes than among s/s homozygotes, but that finding applied only to older white women with late age at onset of depression (Porcelli *et al.* 2012).

Another candidate gene of high interest in predicting antidepressant outcomes encodes methylene tetrahydrofolate reductase (MTHFR), with a known functional polymorphism associated with low enzyme activity. MTHFR catalyzes methylation of folic acid, facilitating its transfer across the blood-brain barrier. The low-activity variant of this enzyme (associated with the T allele at the 677 C > T polymorphism) should, in principle, bear clinical relevance for the subgroup of depressed patients especially likely to respond to supplemental dietary L-methylfolate. However, the sole empirical study testing this otherwise compelling hypothesis found a numerically favorable but statistically nonsignificant advantage for adjunctive L-methylfolate (dosed at 15 mg/day) in improving response rates among T allele carriers (23.1%) versus CC homozygotes (16.4% response) (Papakostas *et al.* 2014). If there is a true difference in L-methylfolate antidepressant response based on MTHFR genotype, the effect is likely a small one.

In schizophrenia, a review of 44 studies examining pharmacogenetic correlates of antipsychotic response found the strongest associations with CYP2D6 metabolizer genotype (Yoshida and Muller 2020). Association studies involving variants of the dopamine receptor gene (*DRD2*) and the 5-HT$_{2A}$ receptor gene (*HTR2A*) have produced more inconsistent findings. Six of nine studies in that review reported a significant association between antipsychotic response and the COMT Val^{158}Met polymorphism (rs4680); two of three studies reported significant associations with the *HTR2A* polymorphism (rs6314), along with several variants of *HTR2C*, and the type-7 metabotropic glutamate receptor gene (*GRM7*). GWAS also have identified a number of candidate genes potentially associated with antipsychotic response, including the genes for multiple EGF-like domains 10 (*MEGF10*); solute carrier family 1, member 1 (*SLC1A1*); protocahedrin 7 (*PCDH7*); contactin-associated protein-like 5 (*CNTNAP5*); TRAF2 and NCK-interacting kinase (*TNIK*); glutamate ionotropic receptor delta type subunit 2 (*GRID2*); and erb-b2 receptor tyrosine kinase 4 (*ERBB4*).

In bipolar disorder, lithium response has been described preliminarily in association with a handful of candidate genes, including *PLCG-1*, *GSK3* ("C" allele associated with response), *XBP1*

("C" allele associated with response), and *NTRK2* ("TT" homozygosity associated with response), as well as mtDNA (Pagani *et al.* 2019).

Replication is needed across essentially all of the aforementioned studies before meaningful recommendations can be made to psychiatrists, who may be eager to embrace pharmacogenetic markers as useful tools for everyday clinical practice.

Table 6-4 summarizes the pros and cons of pharmacogenetic testing for practitioners.

TABLE 6-4. Pros and cons of pharmacogenetic testing in clinical practice

Pros	Cons
Testing provides safety information about specific at-risk groups (e.g., *HLA-B*1502* and Stevens-Johnson syndrome in Southeast Asians; risk for QTc prolongation in poor metabolizer genotypes for cytochrome P450 [CYP] substrates that can prolong QTc).	No robust data exists to predict drug efficacy or response in any psychiatric disorder.
Clinicians can affirm clinical suspicions about lack of efficacy for poor metabolizers of CYP substrates who cannot convert parent drugs to their active metabolites (e.g., venlafaxine and CYP2D6; carbamazepine and CYP3A4; risperidone and CYP2D6), or ultrarapid metabolizers who may need supratherapeutic dosages to achieve efficacy.	The extent to which genetic factors contribute to drug response relative to clinical and other nongenetic determinants is not yet fully understood.
Pharmacogenetic correlates of specific adverse effects (e.g., metabolic dysregulation) may be useful in anticipating specific drug tolerabilities--though current technology does not allow reliable prediction of serious adverse events such as iatrogenic agranulocytosis.	Drug nonresponse due to ultrarapid metabolizer genotypes, or excessive side effects, can be predicted and thus averted by choosing drugs that undergo different metabolic pathways, without necessity of pharmacogenetic testing.
	Single candidate gene strategies appear technologically inferior to genome-wide association studies--but findings from the latter are scant and not replicated.
	Current pharmacogenetic studies often do not systematically account for population stratification and variation in allele frequencies across racial-ethnic-geographic groups, limiting the generalizability of findings.
	Misleading recommendations from pharmacogenetic testing have been reported that contradict clinical observations (e.g., disputed value of a clozapine trial in treatment-resistant schizophrenia) (Rahman *et al.* 2017).

Pros	Cons
	Cost-effectiveness has not yet been demonstrated in replicated findings (Rosenblat *et al.* 2017).

Conclusion

Expert psychopharmacology involves a strong working knowledge of the basic concepts behind pharmacokinetics and pharmacodynamics. It is probably not so useful or important for clinicians to attempt to memorize every CYP enzyme-substrate pairing, the particular dissociation constants of ligand-receptor binding configurations, the magnitude by which bioavailability diminishes after a drug undergoes first-pass metabolism, or the specific data to support or refute the utility of specific pharmacogenetic SNPs. They should instead focus on understanding how to interpret data in these areas, and how to make use of lifelong educational resources, as the field continues to expand in technology and depth of information.

APPENDIX

Pharmacokinetic Parameters of Specific Medications

First-generation antipsychotics

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Chlorpromazine	10%-80%	None	30 hours	CYP2D6	No
Fluphenazine	2.7%	None	15-30 hours	Presumed to be CYP2D6	No
Haloperidol	60%-70%	None	14.5-36.7 hours	Glucuronidation, CYP3A4, CYP1A2	No
Perphenazine	40%	None	9-12 hours	CYP2D6	No
Pimozide	50%	None	29-150 hours	CYP3A4 (primary); CYP1A2 (minor)	No
Thioridazine	50%	None	7-13 hours	CYP2D6	No
Thiothixene	Unknown	None	10-20 hours	CYP2D6	No
Trifluoperazine	100%	None	12.5-13.6 hours	CYP1A2	No

Note. CYP = cytochrome P450.

Second-generation antipsychotics

Agent	**Oral bioavailability**	**Effect of food with oral administration**	**Half-life ($t_{1/2}$)**	**Primary metabolic pathway**	**Renal dosing required?**
Aripiprazole	87%	None	75 hours	CYP2D6, CYP3A4	No
Asenapine	< 2% (oral); 35% (sublingual)	Should not be swallowed[a]	24 hours	CYP1A2; UGT1A4	No
Brexpiprazole	95%	None	91 hours	CYP2D6, CYP3A4	Yes
Cariprazine	52%	None	48-96 hours[b]	CYP3A4 (primary); CYP2D6 (minor)	No
Clozapine	60%-70%	Food lowers C_{max} by 20%	14 hours	CYP1A2, CYP3A4 (primary); CYP2C19, CYP2D6 (minor)	No
Iloperidone	36%	None	18 hours	CYP2D6, CYP3A4	No
Lumateperone	4.4%	High-fat food lowers C_{max} by 33% and increases AUC by 9%	13-18 hours	UGT1A1, UGT1A4, UGT2B15; aldo-keto reductase 1C1, 1B10, 1C4; CYP 3A4, CYP2C8, CYP1A2	No
Lurasidone	9%-19%	[?] 350-calorie meal increases C_{max} threefold	18 hours	CYP3A4	Yes
Olanzapine	60%-65%	None	33 hours	CYP1A2 (primary); CYP2D6, UGT1A4 (minor)	No

Note. AUC = area under the curve; C_{max} = maximum concentration; CYP = cytochrome P450; IR = immediate release; UGT = uridine diphosphate [UDP]-glucuronosyltransferase; XR = extended release.

[a] Manufacturer advises not eating or drinking for 10 minutes after sublingual administration.

[b] Cariprazine has two active metabolites, each with relatively long half-lives: desmethylcariprazine ($t_{1/2}$ = 24-48 hours) and didesmethylcariprazine ($t_{1/2}$ = 1-3 weeks).

Agent	**Oral bioavailability**	**Effect of food with oral administration**	**Half-life ($t_{1/2}$)**	**Primary metabolic pathway**	**Renal dosing required?**
Paliperidone	28%	None	3-17 hours	Mostly renally excreted unmetabolized; some metabolism by CYP3A4 and P-glycoprotein 274	Yes
Quetiapine	100%	IR: none XR: food increases C_{max} by about half; manufacturer recommends ingestion on empty stomach or with only a light meal	6 hours	CYP3A4	No
Risperidone	70%	None	3 hours	CYP2D6	Yes
Ziprasidone	50% (with food)	Greater absorption with food ([?] 500 calories)	6-7 hours	CYP3A4; aldehyde oxidase	No

Note. AUC = area under the curve; C_{max} = maximum concentration; CYP = cytochrome P450; IR = immediate release; UGT = uridine diphosphate [UDP]-glucuronosyltransferase; XR = extended release.

[a] Manufacturer advises not eating or drinking for 10 minutes after sublingual administration.

[b] Cariprazine has two active metabolites, each with relatively long half-lives: desmethylcariprazine ($t_{1/2}$ = 24-48 hours) and didesmethylcariprazine ($t_{1/2}$ = 1-3 weeks).

Monoaminergic antidepressants

Agent	**Oral bioavailability**	**Effect of food with oral administration**	**Half-life ($t_{1/2}$)**	**Primary metabolic pathway**	**Renal dosing required?**

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450; 5-HT = 5-hydroxytryptamine (serotonin); MAOIs = monoamine oxidase inhibitors; NaSSAs = noradrenergic and specific serotonergic antidepressants; NDRI = norepinephrine-dopamine reuptake inhibitor; SSRIs = selective serotonin reuptake inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; TCAs = tricyclic antidepressants; T_{max} = time to peak drug concentration.

[a] Not available in the United States.

[b] Food increases the bioavailability of trazodone but also prolongs time to its peak plasma concentration; when used off-label to treat insomnia, prolonged T_{max} due to ingestion with food may therefore be undesirable.

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Azapirone					
Gepirone	14%-17%	Increases AUC but not C_{max} or T_{max}	5 hours	CYP3A4	Only if CrCl < 50 mL/minute
SSRIs					
Citalopram	80%	None	35 hours	CYP3A4, CYP2C19	Only if CrCl < 30 mL/minute
Escitalopram	80%	None	27-32 hours	CYP2D6, CYP2C19	No data when CrCl < 30 mL/minute
Fluoxetine	60%-80%	None	4-6 days (norfluoxetine: 7-9 days)	CYP2D6	No
Fluvoxamine	50%	None	15-20 hours	CYP2D6, CYP1A2	No data
Paroxetine	30%-60%	None	21 hours	CYP2D6	Only if CrCl<30 mL/minute
Sertraline	44%	None	26 hours	CYP2B6 (primary); CYP2D6, CYP2A4, CYP2C19 (minor)	None

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450; 5-HT = 5-hydroxytryptamine (serotonin); MAOIs = monoamine oxidase inhibitors; NaSSAs = noradrenergic and specific serotonergic antidepressants; NDRI = norepinephrine-dopamine reuptake inhibitor; SSRIs = selective serotonin reuptake inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; TCAs = tricyclic antidepressants; T_{max} = time to peak drug concentration.

[a] Not available in the United States.

[b] Food increases the bioavailability of trazodone but also prolongs time to its peak plasma concentration; when used off-label to treat insomnia, prolonged T_{max} due to ingestion with food may therefore be undesirable.

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
SNRIs					
Desvenlafaxine	80.5%	None	10 hours	UGT1A1	Yes 276
Duloxetine	50%	None	12 hours	CYP2D6, CYP1A2	Only if CrCl < 30 mL/minute
Levomilnacipran	92%	None	12 hours	CYP3A4 (primary); CYP2D6, CYP3A4, CYP2C19, CYP2C8, CYP2J2 (minor)	Only if CrCl<60 mL/minute
Venlafaxine	45%	Food decreases rate but not extent of absorption	4 hours	CYP2D6	Yes
MAOIs					
Isocarboxazid	Not established	None (but must follow tyramine-free diet)	1.5-4 hours	Not fully understood; possible *N*-acetylation	No
Moclobemide	60%-80%	Slightly decreased absorption (T_{max} decreased by about 40 minutes) with food	2-4 hours	CYP2C19, CYP2D6	No 277

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450; 5-HT = 5-hydroxytryptamine (serotonin); MAOIs = monoamine oxidase inhibitors; NaSSAs = noradrenergic and specific serotonergic antidepressants; NDRI = norepinephrine-dopamine reuptake inhibitor; SSRIs = selective serotonin reuptake inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; TCAs = tricyclic antidepressants; T_{max} = time to peak drug concentration.

[a] Not available in the United States.

[b] Food increases the bioavailability of trazodone but also prolongs time to its peak plasma concentration; when used off-label to treat insomnia, prolonged T_{max} due to ingestion with food may therefore be undesirable.

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Phenelzine	Not well established	None (but must follow tyramine-free diet)	11.6 hours	Oxidized to phenylacetic acid and parahydroxyphenyl-acetic acid; acetylation to *N*^{2}-acetylphenelzine is a minor pathway	No
Selegiline transdermal	73%	No pharmacokinetic effect; must follow tyramine-free diet at dosage of 9 mg/day or 12 mg/day	18-25 hours	CYP2B6, CYP2C9, CYP3A4	No
Tranylcypromine	50%	None (but must follow tyramine-free diet)	2 hours	Metabolized via ring hydroxylation and *N*-acetylation; the role of specific metabolic enzymes is not well understood	No
NaSSAs					
Mianserin[a]	20%-30%	None	21-61 hours	CYP2D6, CYP2B6	No
Mirtazapine	50%	None	20-40 hours	CYP2D6, CYP3A4, CYP1A2	Yes if CrCl < 40 mL/minute

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450; 5-HT = 5-hydroxytryptamine (serotonin); MAOIs = monoamine oxidase inhibitors; NaSSAs = noradrenergic and specific serotonergic antidepressants; NDRI = norepinephrine-dopamine reuptake inhibitor; SSRIs = selective serotonin reuptake inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; TCAs = tricyclic antidepressants; T_{max} = time to peak drug concentration.

Lithium and anticonvulsants

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Carbamazepine	75%-85%	None	25-65 hours	3A4	No
Divalproex	Divalproex DR = 100%;	Food slows rate of absorption	9-16 hours	Glucuronidation and mitochondrial b-oxidation	No

Note. AUC = area under the curve; CYP = cytochrome P450; DR = delayed release; ER = extended release; UDP = uridine diphosphate.

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
	divalproex ER = 89%			(primary); CYP2A6, CYP2B6, CYP2C9, CYP3A5 (minor)	
Gabapentin	27%-60%	None	5-7 hours	None	Yes
Gabapentin enacarbil	75%	30%-40% greater exposure (AUC) with food	5.1-6 hours	None	Yes
Lamotrigine	98%	None	25-33 hours	UDP-glucuronidation	No
Lithium	100%	None	24 hours	None	Yes
Oxcarbazepine	> 95%	None	2 hours (active 10-monohydroxy metabolite = 10 hours)	CYP3A4	Yes
Topiramate	27%-59%	None	21 hours	CYP3A4	Yes
Zonisamide	100%	None	63 hours	CYP3A4	No

Note. AUC = area under the curve; CYP = cytochrome P450; DR = delayed release; ER = extended release; UDP = uridine diphosphate.

Stimulants and related drugs for ADHD

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Atomoxetine	63%	None	5.2 hours (21.6 hours in CYP2D6 poor	CYP2D6	No

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450.

[a] Food speeds absorption of immediate-release methylphenidate. Ingestion of extended-release methylphenidate with versus without food does not affect absorption.

Procognitive drugs

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Amantadine	66%-100%	None	17 hours	No appreciable metabolism	Yes, if CrCl < 50 mL/minute
Donepezil	100%	None	70 hours	CYP3A4	No
Galantamine	90%-100%	Food decreases C_{max} by 25% and delays T_{max} by 1.5 hours	7-8 hours	CYP2D6, CYP3A4	Yes, if CrCl < 60 mL/minute
Memantine	100%	None	60-100 hours	*N*-glucuronidation	Yes, if CrCl < 30 mL/minute
Rivastigmine	40%	Food delays absorption and lowers C_{max} and AUC by 30%	1.5 hours	Metabolized primarily via cholinesterase-mediated hydrolysis to the decarbamylated metabolite NAP226-90	No data

Note. AUC = area under the curve; C_{max} = maximum concentration; CrCl = creatinine clearance; CYP = cytochrome P450; T_{max} = time to peak drug concentration.

Vesicular monoamine transporter 2 (VMAT2) inhibitors

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?

Agent	Oral bioavailability	Effect of food with oral administration	Half-life ($t_{1/2}$)	Primary metabolic pathway	Renal dosing required?
Deutetrabenazine	80%	Food increases C_{max} by about 50%	9-10 hours	CYP2D6	No
Valbenazine	49%	Food decreases AUC by about 47%	15-22 hours	CYP3A4/5; [+]-a-dihydrotetrabenazine metabolite partly metabolized by CYP2D6	No

Note. AUC = area under the curve; C_{max} = maximum concentration; CYP = cytochrome P450.

CHAPTER 7

Neuroimaging and Psychiatry

Martin P. Paulus, M.D.

Salvador Guinjoan, M.D., Ph.D.

Researchers utilizing noninvasive in vivo human brain imaging techniques have long searched for objective biological markers for psychiatric disorders, the discovery of which would advance psychiatry from an era of subjective descriptive classification to one of quantitative brain-based measurements (Abi-Dargham and Horga 2016). Yet, objective neuroimaging markers in psychiatry have been elusive; therefore, the impact of neuroimaging-based approaches on pragmatic clinical decision-making in psychiatry is so far extremely limited. Moreover, several methodological issues in the neuroimaging literature have been highlighted in recent years, including small sample sizes and the resulting power failures leading to a "replication crisis" (Button *et al.* 2013; Kharabian Masouleh *et al.* 2019; Poldrack *et al.* 2017; Szucs and Ioannidis 2017), as well as a dependency on analysis pipelines (Botvinik-Nezer *et al.* 2020) and modest test-retest reliability (Esteban *et al.* 2020), which further hinder the potential application of neuroimaging in clinical psychiatry.

The crux of the problem is that many of our findings with neuroimaging approaches are still based on relatively small datasets. In a previous meta-analysis (Feng *et al.* 2022), we showed that effect sizes are vastly overestimated with these small sample sizes and that the results typically do not stabilize until one has reached several hundred participants. Larger population-representative sample studies support the notion that variability in structural and functional brain imaging accounts for only a small percentage of explained variance when a variety of clinical phenotypes are considered. For instance, a 2016 analysis of UK Biobank data revealed that the fusiform gyrus and amygdala activation related to a face processing task accounted for a maximum of 1.8% of the variance of 1,100 non-neuroimaging variables (Miller *et al.* 2016). These findings are in line with emerging results from the ABCD Study, such as the association between screen media behavior and structural MRI characteristics (Paulus *et al.* 2019). Together, these findings suggest that individual processing differences as measured by neuroimaging techniques (or other methods) could account for little symptomatic or behavioral variance (Paulus and Thompson 2019).

In this chapter we review the most robust findings in structural and functional neuroimaging as they relate to psychiatric disorders. Following the available literature, the bulk of information will refer to MRI methods, with a briefer mention of PET, a technique that is older, but less commonly used, than MRI. The strategy taken here is to use only meta-analyses of neuroimaging findings to highlight which neural substrates are affected across disorders and within a particular disorder, and which brain areas change as a function of treatment. Although some have criticized the excessive use of meta-analyses (Ioannidis 2010; Ioannidis *et al.* 2015), these approaches still provide qualitatively better evidence than do small, single-site neuroimaging experiments. However, this is changing with the advent of epidemiologically based neuroimaging like ABCD (Volkow *et al.* 2018) or the UK Biobank (Miller *et al.* 2016), although the diagnostic assessments of these studies rarely are as intense and detailed as they are in many of the smaller clinical studies.

There are a couple of caveats that one needs to keep in mind when examining the presented evidence. First, most of the meta-analyses are based on case-control, cross-sectional studies, which have a limited ability to identify causal factors underlying the observed clinical presentation. Therefore, most--if not all--of these studies are associative in nature and will suffer significant limitations in determining whether the neuroimaging findings are causes, consequences, or non-disease-relevant associated observations. Second, meta-analyses necessarily must pool across different approaches that range from acquisition of the imaging data to analyses arriving at the summary statistics. Therefore, heterogeneity is baked into the results of the meta-analysis from the start. Third, meta-analyses cannot fundamentally overcome some of the imaging limitations. For example, although the statistical characteristics of structural neuroimaging such as reliability and external validity have been examined in detail and were found to be at a level similar to what is being observed for standard clinical instruments, the reliability and external validity of functional neuroimaging data are much more debated. Fourth, it is increasingly clear that our diagnostic categories do not simply map onto differential structural or functional changes in the brain. The Research Domain Criteria (RDoC) approach (Insel *et al.* 2010) was an initial attempt to separate psychiatric disorders into different transdiagnostic disease processes. This approach has had some success but has also faced significant challenges (Bzdok and Meyer-Lindenberg 2018; Conway *et al.* 2019; Hennessey *et al.* 2018). For example, diagnostic categories such as major depressive disorder not only are characterized by dysfunctional processes (e.g., reduced ability to process rewarding events) but also exhibit an episodic dysfunction of positive and negative valence processing (i.e., during periods of depression, individuals have difficulty processing "good" or "bad" events appropriately). This overview of neuroimaging and psychiatry will take a current, state-of-the-art critical view of what has been accomplished based on both structural and functional MRI, and, to a lesser extent, PET approaches. The goal is to provide insights into the emerging patterns of brain-associated changes in psychiatric disorders as well as specific changes that may help to identify novel targeted interventions based on neuromodulatory tools.

Process-Specific Approaches

The basic experimental approach of neuroimaging research is to define a particular process (e.g., the processing of emotions as expressed in human faces), examine the change in brain signaling during this process, and--using thoughtful experimental manipulation or group comparisons--delineate a model that describes how the brain implements this particular process. However, defining a "process" is a highly heuristic endeavor, and we are far from understanding the fundamental "atomic" processes that make up our cognitive and emotional experiences. Functional neuroimaging measures mass action of neural tissue when individuals process information originating from the outside world or from the inside of the body. The assumption is that greater or lesser "activation" is due to greater or lesser engagement of mass action during a specific process. Thus, greater or lesser engagement could be due to a) less-or more-efficient processing of information (i.e., neural activation is needed to accomplish a process); b) greater or lesser involvement due to "deeper" or "more extensive" or "shallower" or "more restricted" processing of the information; or c) engagement of different brain systems in processing the information, which results in greater or lesser activation of the neural tissue under study. Although intuitive, much of the relationship between neural processing intensity and intensity of the affective or cognitive process is still unclear (Lebreton *et al.* 2019).

In this section, we review a few processes that are critically important for different psychiatric disorders and for which meta-analyses have provided robust evidence for their underlying neural substrates. It is arguable that each of these processes could be split further into smaller components, which may provide another way of identifying more targeted differences in individuals with psychiatric disorders.

One of the most important processes for psychiatric disorders is our ability to process emotions. Meta-analyses show that there is currently no evidence that emotion processing in the brain falls in line with what has been called the *bivalent hypothesis*, which proposes that different brain systems compute positive or negative emotions, or the *bipolarity hypothesis*, which proposes that brain systems increase or decrease with a particular positive or negative emotion, respectively. Instead, it appears that brain activations fall more in line with the *affective workspace* hypothesis, which suggests that positive and negative affect are supported by a flexible set of valence-general regions (Lindquist *et al.* 2016). Many experimental approaches probing affect involve processing of facial expressions, which is supported by a network of structures, including the visual, limbic, and temporoparietal and prefrontal areas; the putamen; the cerebellum; and, most importantly, the amygdala and insula (Fusar-Poli *et al.* 2009). As will become evident once transdiagnostic or diagnostic groups are considered, it should not be surprising that the function of many of these brain areas is significantly affected in psychiatric disorders.

Anticipation is an important component of emotion processing and is supported by the insula, cingulate, amygdala, thalamus, and caudate (Andrzejewski *et al.* 2019), areas that are sensitively affected in mood and anxiety disorders. (Figure 7-1 summarizes the brain areas involved in processing anticipatory emotional information.) In comparison, it does not appear that emotion-based approach or avoidance behavior can be related to a delineated set of neural substrates; however, there appears to be a shift from forebrain to midbrain as threat-related stimuli become more imminent (Patrick *et al.* 2019). In the context of processing positive or negative events, social reward plays an important role in most psychiatric conditions and involves a number of brain regions, most notably the ventral striatum. Not surprisingly, some diagnostic groups show moderately attenuated processing of social rewards, whereas others (e.g., bipolar disorders, eating disorders, sexual disorders) exhibit increased activation to social rewards (Aldridge-Waddon *et al.* 2020). Fear conditioning and extinction have been used to explain anxiety-related disorders in terms of increased conditioning, attenuated extinction, or overgeneralization of conditioned stimuli. Several meta-analyses have shown that a network of brain regions, including in particular the anterior insular cortex and anterior cingulate, processes the conditioning and extinction processes (Fullana *et al.* 2016). In comparison, a network of cingulo-opercular, frontoparietal, striatal-thalamic, and midbrain regions is involved in positive generalization, whereas ventromedial prefrontal cortex, hippocampus, middle temporal gyrus, and angular gyrus process negative generalization (Webler *et al.* 2021). Taken together, a network of brain structures, most notably anterior insula and anterior cingulate, is commonly found in different components of emotion processing that are relevant for psychiatric disorders.

On the other hand, alterations in cognitive processes, which are frequently associated with psychiatric disorders such as schizophrenia, involve a different set of brain structures, notably the left superior temporal gyrus and left posterior middle temporal gyrus (Wensing *et al.* 2017). In comparison, perseverative cognition such as worrying or rumination involves the left middle frontal gyrus, left inferior frontal gyrus, and left anterior insula (Weber-Goericke and Muehlhan 2019). Others have reported that in individuals with psychiatric disorders, ruminative cognitions are also associated with activation in the medial frontal gyrus, cingulate gyrus, insula, and posterior cingulate cortex (Makovac *et al.* 2020). Altered perceptions such as auditory or visual hallucinations are associated with activation in the bilateral inferior frontal gyrus, bilateral postcentral gyrus, and left parietal operculum, whereas the propensity to experience such perceptual abnormalities occurs in individuals with altered processing within the left superior temporal gyrus, left middle temporal gyrus, anterior cingulate cortex, and left premotor cortex (Kuhn and Gallinat 2012). These findings point toward the notion that altered cognitive and perceptual symptoms are processed by systems typically found to be important for nonclinical populations. Therefore, one might conclude that clinically symptomatic cognition and perception are an excessive extension of normally occurring processes. Figure 7-2 summarizes the brain areas involved in cognitive and perceptual processing.

Transdiagnostic Approaches

Transdiagnostic approaches have gained a lot more attention since the National Institute of Mental Health began the RDoC project in 2009 to develop a research classification system for mental disorders based on neurobiology and observable behavior (Cuthbert and Insel 2013). The RDoC initiative highlights the need to 1) determine the relationships among different units of analysis (i.e., genes, molecules, cells, circuits, physiology, behavior, self-report, and paradigms) and 2) transcend traditional diagnostic groups to adequately capture the variation of domains in clinical populations that can be mapped across units of analysis. This approach is--to some degree--supported by the finding that brain structural abnormalities in major depressive disorder, bipolar disorder, schizophrenia, and OCD are highly correlated (Radonjic *et al.* 2021), which can be captured by one shared latent underlying factor that can explain as much as 80% the brain structural variance of each disorder (Opel *et al.* 2020). Specifically, gray matter loss across diagnoses can be seen in the dorsal anterior cingulate, right insula, and left insula and is associated with poorer cognitive functioning (Goodkind *et al.* 2015). Whereas altered cognitive control processing across disorders is evident in the left prefrontal cortex as well as the anterior insula, dorsal cingulate cortex, right ventrolateral prefrontal cortex, right intraparietal sulcus, and midcingulate/presupplementary motor area (McTeague *et al.* 2017), affective processing abnormalities have been associated with altered activation in the amygdala, the hippocampal or parahippocampal gyri, the dorsomedial or pulvinar nuclei of the thalamus, and the fusiform gyri, as well as the medial and lateral dorsal and ventral prefrontal regions

(McTeague *et al.* 2020). Recently, transdiagnostic interoceptive dysfunctional processing has been related to altered insula activation (Nord *et al.* 2021). In comparison, across task-based functional MRI (fMRI) the most pronounced transdiagnostic differences are found in the amygdala and caudate nucleus, hippocampus, putamen, and nucleus accumbens (Sprooten *et al.* 2017). In summary, both structural and functional neuroimaging studies support the idea that general and task-specific processing dysfunctions occur transdiagnostically in brain areas that have been previously identified as critical for integrative processing. However, much work is still necessary to link such transdiagnostic brain structure and function abnormalities to clinical parameters such as risk for and severity and consequences of the disease process.

Diagnosis-Specific Imaging Findings

Schizophrenia

Most neuroimaging meta-analyses have been conducted for schizophrenia, which has resulted in a solid body of evidence of both structural and functional alterations that have been associated with the disorder in general and with symptoms or outcomes specifically. Structural MRI meta-analyses show that intracranial volume and total brain volume are decreased by 2% in medicated schizophrenia patients and that the decrease is even more pronounced in medication-naive individuals (Haijma *et al.* 2013). Medicated individuals show decreased volumes of the left lateral temporal cortex, left inferior frontal gyrus, superior frontal gyrus extending to the left middle frontal gyrus, and right rectal gyrus; in comparison, relative volumetric increases are found in the left dorsal anterior cingulate cortex, left ventral anterior cingulate cortex, and right putamen (Torres *et al.* 2013). Moreover, individuals with schizophrenia have significantly smaller hippocampi (Haukvik *et al.* 2018). Although there has been vigorous debate about the heterogeneity of the disorder, analysis of the variability among imaging findings did not reveal greater imaging variability, especially for some of the pronounced findings such as ventricular volume increases (Kuo and Pogue-Geile 2019). Multimodal imaging analysis provides evidence for considerable overlap between anatomic and functional changes in brain areas including frontotemporal regions, bilateral medial posterior cingulate/paracingulate gyrus, bilateral insula, basal ganglia, and left cerebellum (Gao *et al.* 2018). Beyond the disorder stage, ultra-high-risk individuals exhibit greater gray matter volumes in the bilateral cingulate, right fusiform gyrus, left superior temporal gyrus, and right thalamus but decreased volumes in the right gyrus rectus, right superior frontal gyrus, and left superior frontal gyrus (Ding *et al.* 2019). On the other hand, the schizophrenia deficit state has been associated with a profound reduction in gray and white matter volume (Chee *et al.* 2020). Taken together, structural imaging meta-analyses find extensive cortical volume reductions and ventricular size increases, with some of these changes predating illness onset, and others (more widespread changes) being associated with the deficit stage of the disorder.

Functional neuroimaging meta-analyses have revealed substantial deficits in processing as well as related attenuated brain activation during *cognitive control* in the left dorsolateral prefrontal cortex, rostral/dorsal anterior cingulate cortex, left thalamus, and inferior/posterior cortical areas (Minzenberg *et al.* 2009); *working memory* in the bilateral dorsolateral prefrontal cortex and posterior parietal cortex as well as the anterior insula, anterior cingulate cortex, and supplementary motor area (Wu and Jiang 2020); *auditory processing* in the left primary auditory cortex and right rostral prefrontal cortex (Kompus *et al.* 2011); *facial processing* in the bilateral amygdala, parahippocampal gyrus and fusiform gyrus, right superior frontal gyrus, and lentiform nucleus (Li *et al.* 2010) as well as the insula (Dong *et al.* 2018); *emotion processing* in the bilateral amygdala, visual processing areas, anterior cingulate cortex, dorsolateral frontal cortex, medial frontal cortex, and subcortical structures (Anticevic *et al.* 2012; Taylor *et al.* 2012); *neutral affective material processing* in the left and right amygdala and parahippocampus and the left putamen, hippocampus, and insula (Dugre *et al.* 2019); and across task domains in subcortical basal ganglia (Bernard *et al.* 2017). Beyond task-based and location-specific changes, it appears that functional activation characteristics are also changed in terms of underlying network structure

(Crossley *et al.* 2016), particularly with regard to local connectedness (Kambeitz *et al.* 2016). Finally, it appears that cognitive retraining does improve activation patterns in prefrontal areas, but its effects are modest and variable (Mothersill and Donohoe 2019). Thus, like the structural findings in schizophrenia, functional imaging studies show a widespread attenuation that involves process-specific areas but also includes task-independent structures such as the prefrontal cortex, subcortical structures, and limbic areas.

Bipolar Disorder

Early findings of structural abnormalities (Strakowski *et al.* 1999) were subsequently replicated in meta-analyses finding robust structural differences between individuals with bipolar disorder and comparison subjects; these differences involve areas that are important for regulation of emotions, such as limbic areas (Houenou *et al.* 2011), but also the right ventral prefrontal cortex, insula, temporal cortex, and claustrum (Selvaraj *et al.* 2012). Relative to nonpsychotic patients with bipolar disorder, psychotic bipolar patients show greater reductions in the prefrontal, temporal, and cingulate cortices as well as in the precentral gyrus and the insula (Wang *et al.* 2018).

Interestingly, two meta-analyses found evidence for lithium treatment-modulated structural brain differences in the hippocampus (Hajek *et al.* 2012) and global brain volume (Sun *et al.* 2018). The predominant functional changes observed in patients with bipolar disorder involve brain regions that are important for emotion processing, with increased activation in ventral limbic brain regions (Houenou *et al.* 2011). Moreover, during emotion processing, youths with bipolar disorder show greater convergence of hyperactivation in the inferior frontal gyrus and precuneus than do adults with bipolar disorder (Wegbreit *et al.* 2014). Extending these findings to the relatives of individuals with bipolar disorder, these individuals show greater activation in frontostriatal regions but reduced activation in the parietal cortex during cognition, as well as increased activation in the amygdala during emotional processing and in the orbitofrontal cortex during reward, relative to healthy control subjects (Cattarinussi *et al.* 2019). These findings are consistent with the idea of a preexisting imbalance of cognitive/affective processing, which is further supported by similar changes in individuals with first-episode mania (Keramatian *et al.* 2021). In summary, both structural and functional neuroimaging findings in bipolar disorder implicate impaired emotion processing, which may exist prior to illness onset and occurs subtly in family relatives, but which can also be affected by treatment.

Depression

Structural neuroimaging meta-analyses have shown that in comparison with healthy control subjects, individuals with depression have lateral ventricle enlargement; larger cerebrospinal fluid volume; and smaller volumes of the basal ganglia, thalamus, hippocampus, frontal lobe, orbitofrontal cortex, and gyrus rectus (Kempton *et al.* 2011). Others reported thinner cortical gray matter in the orbitofrontal cortex, anterior and posterior cingulate, insula, and temporal lobes in depressed patients compared with healthy controls (Schmaal *et al.* 2017). A relatively consistent feature has been bilateral hippocampal atrophy (Santos *et al.* 2018), which was also observed during symptom-free intervals (Kempton *et al.* 2011). In comparison, functional neuroimaging findings have been more variable. Initially, there was relatively little evidence for a common task-based fMRI network dysfunction (Gray *et al.* 2020). However, other analyses yielded hypoactive clusters in the anterior insular and rostral anterior cingulate cortex (Sacher *et al.* 2012) as well as the subgenual anterior cingulate cortex (Diener *et al.* 2012). Two specific processing dysfunctions can be observed in participants with depression relative to healthy comparison subjects. First, there is increased activation associated with social cognitive processing in areas of the brain related to emotions, such as the limbic structures, but decreased activity in the frontal regions of the brain (Cusi *et al.* 2012). Second, there is increased brain activation associated with negative stimuli, with heightened responses in the amygdala, insula, and dorsal anterior cingulate cortex, but reduced activation in the dorsal striatum and dorsolateral prefrontal cortex (Hamilton *et al.* 2012). A distinguishing feature between individuals with and without depression is the level of activation in the lateral frontal areas of the brain, which appears to respond to therapeutic interventions (Graham *et al.* 2013). Resting state fMRI meta-analyses have found increases in intrinsic activity in the anterior cingulate cortex (Zhou *et al.* 2017), and these changes appear to be sufficiently strong to yield a relatively high separation of groups based on machine learning approaches (Kambeitz *et al.* 2017).

There is a paucity of meta-analyses of PET and SPECT studies in depression, and those that have been published have focused on three main themes: regional brain metabolism, serotonin neurotransmission, and neuroinflammation. The latter two areas of research cannot be addressed with MRI and therefore are of greater pathophysiological interest. One meta-analysis has examined serotonin$_{1A}$ receptor (5-HT$_{1A}$) alterations in depression (Wang *et al.* 2016). These authors concluded that a significant, albeit small, effect was the reduction of 5-HT$_{1A}$ receptors in middle temporal structures. An earlier study of 5-HT transporters (Gryglewski *et al.* 2014) found reductions in 5-HT transporter density in the midbrain and amygdala that were not detected in individual PET or SPECT studies; the decrease in 5-HT transporters in the amygdala was related to severity of depression. A review of in vivo molecular studies of serotonin neurotransmission in individuals with suicidal behavior offered inconsistent results (Desmyter *et al.* 2011). Finally, a recent meta-analysis of studies focusing on central inflammation, an important conceptual avenue for depression pathophysiology (Enache *et al.* 2019), showed that PET studies of translocator protein, a central inflammation marker, revealed significant abnormalities in the anterior cingulate and temporal cortices in major depressive disorder. In summary, although structural neuroimaging findings have been relatively solid, functional changes appear to be more variable, but the findings seem to converge on differences within the medial wall of the cortex, including the anterior cingulate, across different affective processes.

Anxiety

Although no meta-analyses of structural neuroimaging studies specifically focused on anxiety disorders have been conducted as of this writing, there is converging evidence from various functional neuroimaging meta-analyses of a consistent dysfunction of several core neural structures. In one of the earliest meta-analyses across task-related fMRI studies, anxiety disorders were found to be associated with hyperactivity in the amygdala, insula, anterior cingulate, and prefrontal cortex (Etkin and Wager 2007). Others observed that some of the same structures (Gentili *et al.* 2016) and those involved in facial processing, including the bilateral amygdala, globus pallidus, superior temporal sulcus, visual cortex, and prefrontal cortex, were altered in individuals with social anxiety disorder (Bruhl *et al.* 2014). A slightly different pattern can be found in OCD, with increased activation in the bilateral amygdala, right putamen, orbitofrontal cortex extending into the anterior cingulate and ventromedial prefrontal cortex, and middle temporal and left inferior occipital cortices during emotional processing (Thorsen *et al.* 2018). There does not seem to be a fundamentally different functional activation pattern whether the anxiety is experimentally induced in those without anxiety disorder or is observed as part of the illness (Chavanne and Robinson 2021). Although PTSD is technically no longer considered an anxiety disorder, meta-analyses of individuals with PTSD have revealed a similar pattern of functional abnormalities. Specifically, exaggerated activation to trauma stimuli was found in the midline retrosplenial cortex and precuneus, pregenual/anterior cingulate gyrus, and bilateral amygdala, while less activation was found in the bilateral temporal gyri and extrastriate area (Sartory *et al.* 2013). In addition, general hyperactivity during a functional task has been reported for the bilateral insula and cingulate cortex as well as for the parietal, frontal, and limbic areas (Boccia *et al.* 2016). Furthermore, structural neuroimaging

meta-analyses involving adults with PTSD have revealed reduced total corpus callosum areas, reduced total cerebral and intracranial volumes, and reduced total hippocampus, amygdala, and frontal lobe volumes (Milani *et al.* 2017), and similar reductions in these areas have been reported among pediatric patients with PTSD (Kribakaran *et al.* 2020). In summary, a core network of amygdala, insula, and midline prefrontal cortex has been found to differ both structurally (for PTSD) and functionally (for anxiety disorders) from the network in healthy comparison subjects.

Substance Use Disorders

Structural meta-analyses show that across all substances, convergent pathology was evident in the gray matter of the insula, anterior cingulate cortex, putamen, and thalamus, and in the white matter of the thalamic radiation and internal capsule bundle (Pando-Naude *et al.* 2021). Moreover, decreases in gray matter have also been reported in the bilateral prefrontal cortex, bilateral insula, bilateral rolandic operculum, left superior temporal gyrus, and right Heschl gyrus, while increases in gray matter have been found in the right lingual gyrus and right fusiform gyrus (Zhang *et al.* 2021). So far, however, studies in at-risk individuals have not been able to find consistent structural abnormalities (Tervo-Clemmens *et al.* 2020). A similar set of structural abnormalities have been implicated in alcohol use disorder, including reduced gray matter in the corticostriatal-limbic networks (Li *et al.* 2021), especially the bilateral insula, superior temporal gyrus, striatum, dorsal lateral prefrontal cortex, precentral gyrus, anterior cingulate cortex, left thalamus, and right hippocampus (Yang *et al.* 2016). Not surprisingly, alcohol cue-induced enhanced functional activation has been reported for limbic and prefrontal regions, including the ventral striatum, anterior cingulate, and ventromedial prefrontal cortex, as well as the posterior cingulate, precuneus, and superior temporal gyrus (Schacht *et al.* 2013). In comparison with healthy control subjects, individuals with substance or alcohol use disorders show core structural and functional abnormalities in brain regions involved in processing the importance and value of the substance consumed, such as the insula, cingulate, and ventromedial prefrontal cortex. Similar abnormalities are also observed in subcortical structures, such as the striatum.

Neuroimaging Effects of Treatment

Several meta-analyses have been conducted to examine the effects of interventions to determine which neural substrates are affected and what patterns of activity might predict a positive response to treatment, and to identify possible targets for future neuromodulatory treatments. Task-based functional neuroimaging studies show that activations in the dorsomedial prefrontal cortex and in the posterior cingulate gyrus/precuneus change as a function of psychotherapy (Messina *et al.* 2013). In a meta-analyses of changes in brain activity accompanying psychological therapy based on both resting-state and task-based studies, there were decreases in activation in the anterior cingulate/paracingulate gyrus, inferior frontal gyrus, and insula after therapy, with changes in activation in the cuneus being predictive of subsequent symptom change (Marwood *et al.* 2018). Improved emotion regulation after psychotherapy is associated with activation in the dorsomedial prefrontal cortex and posterior cingulate gyrus/precuneus (Messina *et al.* 2013). In social anxiety disorder, activation in both the frontal and parietal cortical areas and the insula and cingulate cortex change as a function of either behavioral or pharmacological treatment (Li *et al.* 2016). Some have reported that perigenual anterior cingulate cortex activation was most robustly associated with repetitive transcranial magnetic stimulation (rTMS) treatment (Long *et al.* 2020). In a meta-analysis that included results from 20 functional imaging studies and 9 structural neuroimaging studies, Fu *et al.* (2013)) reported that increased baseline activity in the anterior cingulate was associated with a higher likelihood of improvement, while increased baseline activation in the insula and striatum was linked to a poorer clinical response. Structural neuroimaging studies have shown that a decrease in right hippocampal volume is a significant predictor of poorer treatment response. In another meta-analysis of psychotherapy treatment studies focused on neuroimaging to measure changes in patients with major depressive disorder, Sankar *et al.* 2018) found increased activity in the left rostral anterior cingulate posttreatment in patients and decreased activity in healthy control subjects. On the other hand, in a meta-analysis examining changes in brain metabolism related to various treatments for major depressive disorder (e.g., selective serotonin reuptake inhibitors, electroconvulsive therapy, rTMS), Chau *et al.* 2017) failed to find a consistent pattern for these treatments' effects in reducing depression.

Taken together, these findings suggest that among the core neural substrates that change after treatment are those that have also been observed to transdiagnostically differ from those of healthy comparison subjects in task-based activation studies, including the anterior cingulate and the prefrontal and parietal cortices (Figure 7-3). These findings suggest that although certain brain structures show treatment-relevant plasticity, there is currently limited evidence for treatment-specific networks that could become targets of future interventions.

Conclusion and Future Directions

Several robust findings have emerged from the available meta-analyses of neuroimaging findings on neural substrates across psychiatric disorders. First, a core set of neural substrates show both structural and functional abnormalities across diagnoses and cognitive or affective processes. These include the cortical midline--most notably the different parts of the anterior cingulate--and the anterior insula. Functionally, these areas have been attributed to what has been termed the *salience network* (Seeley *et al.* 2007) but what others have termed *limbic motor cortex* and *limbic sensory cortex* (Craig 2003). These regions of the brain play a role in assigning importance or significance to the information being processed by the brain. They also aid in coordinating actions that are suitable responses to the importance of the information. It is notable that these areas are also among those that are sensitive to treatment effects, suggesting that these areas are at least partially responsible for the processes that underlie symptomatic phases of psychiatric disorders. The strongest empirical evidence for the role of the salience network is found in mood and anxiety disorders, which are characterized by an exaggerated activation across tasks during the symptomatic stages of these conditions. In addition, the structural and functional abnormalities observed in different disorders are consistent with the processes that are responsible for

the underlying symptoms. For example, content-related cognitive processing dysfunctions such as delusions, worrying, or repetitive negative thinking involve areas of the temporal cortex that are important for speech and memory. Similarly, auditory hallucinations are processed in the auditory cortex and show exaggerated activation patterns in individuals with schizophrenia. Lastly, enhanced cue reactivity, an important part of substance use abnormalities, is observed in subcortical areas that are critically important for reward-related processing. Taken together, these findings support the idea that processing abnormalities in psychiatric disorders reflect exaggerated or attenuated processes in brain structures that are important for these processes in healthy individuals. However, secondary brain areas often coactivate with these primary areas, suggesting that the symptomatic phases of a psychiatric illness reflect dysregulatory networks.

Further work is needed to better understand the nature of the brain processing dysfunctions that underlie psychiatric disorders. Areas that warrant focus include making better connections between structural MRI findings and the underlying anatomy and histology (Weinberger and Radulescu 2021), considering nonspecific imaging effects of pharmacological agents such as lithium (Lucini-Paioni *et al.* 2021), and better conceptualizing what resting state functional neuroimaging represents. In addition, the lack of meta-analytic findings from longitudinal imaging studies with psychiatric patients during different phases of their illness makes it very difficult to draw an accurate image of how brain function waxes and wanes during symptomatic and asymptomatic disease phases. In addition, we have only a rudimentary understanding of structural and functional brain plasticity in response to external influences such as stressors, changes in lifestyles, or relationships. Clinically, these factors are important determinants of change in psychiatric conditions, yet there is virtually no systems-level neuroscientific understanding of how these influences lead to exacerbations of the illness. Meta-analytic approaches can provide insights about "central tendencies"--that is, how an individual with a particular diagnosis might differ on average from a healthy comparison subject. However, very little can be gleaned about individual differences, subgroups, or illness heterogeneity. Although it has been difficult to establish disease heterogeneity, it seems clear that psychiatric diagnoses are not uniform entities and may consist of mixtures of processing dysfunctions that share a similar symptomatic appearance. This many-to-one mapping has been cited as one of the main challenges in better understanding the underlying neurobiological processes of psychiatric disorders (Paulus and Thompson 2019). Future analyses may need to use alternative approaches to begin to delineate robust subgroups of disorders with shared structural or functional neuroimaging characteristics. Much work will need to be done to obtain a more dynamic understanding of structural and functional neuroimaging characteristics of psychiatric disorders.

Several meta-analyses have shown that predicting group membership in a particular diagnostic category or predicting outcome using structural or functional neuroimaging data is possible in principle. Yet there is no current structural or functional neuroimaging procedure in place in a clinical setting to assist in determining a patient's diagnosis or prognosis. There are several reasons for this. First, despite these proof-of-principle findings, and even though meta-analyses are available, much uncertainty still exists as to how generalizable these findings are, how well they stack up once multiple disease groups are considered, and how robust these approaches can be in a clinical setting. Second, there is fundamentally a differential actionability problem. If a diagnosis were to be made using neuroimaging, what different actions would one take to optimize clinical outcomes? There are no studies that show convincingly that neuroimaging-assisted diagnosis or prognosis results in measurably better outcomes for patients. These studies are very difficult to do because they would need to be conducted in multiple sites, using a randomized controlled trial design, and to have prespecified action plans and outcomes. However, short of such evidence, the ultimate utility of neuroimaging for clinicians is an aspirational goal.

Personalized Medicine in Psychiatry

Giampaolo Perna, M.D., Ph.D.

Charles B. Nemeroff, M.D., Ph.D.

The Global Burden and the Unmet Needs of Psychiatric Disorders

The 2019 Global Burden of Diseases, Injuries, and Risk Factors Study estimated that mental and addictive disorders, mainly depressive disorders, are a primary cause of nonfatal burden (Abbafati *et al.* 2020) and account for 19% of all years lived with disability (Rehm and Shield 2019).

Despite a vast array of pharmacological and nonpharmacological therapeutic options, the clinical and functional outcomes of mental disorders remain unsatisfactory (Caldirola and Perna 2019). This is partly because reliable methods for identifying the most effective treatment for each patient remain elusive.

Until the twentieth century, medical practice was based on careful observation and clinical judgment. Thereafter, clinical practice guidelines, founded on the principles of evidence-based medicine, emerged, with recommended clinical and therapeutic choices based on a systematic assessment of the available evidence supported by committees of experts

(Lee *et al.* 2020). Although these guidelines represented an improvement with respect to subjective opinions, treatment recommendations were founded on the average response of the clinical population participating in randomized clinical trials without relating the response to specific individual characteristics. Moreover, it was found that evidence-based practices take 17 years, on average, to be incorporated into the health care routine, and only about half of them are widely used in the clinical setting (Bauer and Kirchner 2020). Clinician cognitive factors, such as confirmation bias (i.e., the tendency to search for, interpret, and recall information in

a way that confirms one's prior beliefs), are thought to contribute to the delay in implementation of clinical practice guidelines (Perna and Nemeroff 2022).

Personalized Medicine: A New Approach

Recently, attention has shifted toward the personalized or precision medicine approach that aims to tailor the best diagnostic and treatment decisions for each patient by integrating clinical, biological, and environmental factors (Perna and Nemeroff 2017). Personalized medicine aims to predict an individual's susceptibility to disease, achieve an accurate diagnosis, and select the best therapeutic option for each person to increase the likelihood of effective response and reduce the occurrence of adverse effects (Sugeir and Naylor 2018).

Personalized predictive models of diagnosis and outcomes are based on the collection of very-large-scale data (so-called big data) that are analyzed using advanced computational tool kits capable of making a prediction from such information (e.g., machine learning methods) (Sugeir and Naylor 2018).

Before being considered and applied in the field of psychiatry, personalized medicine yielded significant breakthroughs in oncology in a study in which the administration of the monoclonal antibody trastuzumab only to the subgroup of women who were HER2-positive was an example of a treatment "personalized" to patients who would benefit the most (Hingorani *et al.* 2013).

The National Research Council found the original term *personalized medicine* to be equivocal, as it implies that unique treatments can be designed for each individual; thus, they suggested that it be changed to *precision medicine* (National Research Council 2011). Although several authors use the terms *precision medicine* and *personalized medicine* synonymously, a recent literature review indicated that *personalized psychiatry* has been more often used in studies addressing mental disorders over a broad range of topics (clinical, biological, and therapeutic) (Perna *et al.* 2020c). Alternatively, the term *precision psychiatry* has been mainly used in investigations of the purely biological context of mental diseases.

Current Difficulties in Personalized Medicine in Psychiatry

In contrast to many medical illnesses, psychiatric disorders are inherently complex because they are related to brain dysfunctions at multiple levels (from neuron to brain connectivity) and amply intertwined with social, cultural, and experiential factors. This peculiarity makes the development of *personalized medicine in psychiatry* (PMIP) even slower and more challenging than in other medical fields.

The Challenge of Psychiatric Disorder Diagnosis

The currently available diagnostic tools DSM-5-TR (American Psychiatric Association 2022) and ICD-11 (World Health Organization 2022) fail to reflect the actual biological processes believed to underlie the identified disorders because they are mainly based on observable behaviors as well as self-reported emotions and thoughts. Despite this limitation, DSM-5-TR and ICD-11 organize the clinical observations in categorically distinct psychopathological entities constituting one of the cornerstones of therapeutic decisions in clinical practice. However, clinical and research evidence has demonstrated that the categorical approach fails to fully express the complexity of mental illness, which often occurs as combinations of several dimensional psychological alterations are sometimes shared by different disorders (Craddock and Owen 2005).

These drawbacks led to the development of the so-called dimensional approach, which defines psychiatric disturbances using a set of psychopathological dimensions encompassing a wide range of severity, from normality to the full expression of the dimension (Krueger and Bezdjian 2009). The potential clinical advantage of replacing the current categorical diagnostic system with a dimensional classification system has long been debated (Krueger and Bezdjian 2009). However, the dimensional scores used to directly make diagnoses need to overcome several limitations associated with the currently available dimensional measures to create specific patterns of independent and diagnostically relevant dimensional scores.

An innovative approach that is based on dimensions rather than categories is the Research Domain Criteria (RDoC) initiative (Insel *et al.* 2010), a classification system based on "dimensions of observable behavior and neurobiological measures" (Cuthbert 2015). The RDoC starts from the basic dimensions of behavior and cognitive/affective processing based on the biological systems and then considers psychopathology as a varying degree of abnormality in these systems, incorporating information from molecular factors to social determinants (Carcone and Ruocco 2017). It is noteworthy that the RDoC framework is a work in progress; thus, it consists of an initial panel of hypotheses that need to be tested and possibly reformulated based on the growth of our understanding. In spite of considerable investment in the RDoC initiative by the National Institute of Mental Health, the framework has fundamentally failed, with none of the funded research producing advances in either diagnosis or treatment.

Finding Biomarkers

The complexity of the diagnostic processes used for psychiatric disturbances makes it difficult to find a biomarker, which is described as "a defined characteristic that is measured as an indicator of normal biological processes, pathogenic processes, or biological responses to an exposure or intervention, including therapeutic interventions" (FDA-NIH Biomarker Working Group 2021, p. 45).

In psychiatric disorders, the biological systems that have been the focus of most investigations are the inflammatory, neurotransmitter, neuroendocrine, neurotrophic, and metabolic systems. In the so-called omics approach, each dysregulated system can be evaluated at different biological levels, from genomics and epigenomics through transcriptomics and proteomics to metabolomics, which are collectively referred to as "multi-omics" (Olivier *et al.* 2019).

In PMIP, the information obtained from the different omics platforms is integrated with clinical data to predict forthcoming disease, diagnostic precision, and targeted prescription of the existing drugs. Omics technologies (i.e., next-generation sequencing for genomics and transcriptomics and mass spectrometry for proteomics and metabolomics) allow collection, in a single experiment, of a huge amount of data, such as billions of genome base pairs, the entire set of cell/tissue proteins, or low-molecular-weight metabolites (e.g., amino acids, lipids, and sugars) (Sethi and Brietzke 2015).

Information and Communications Technologies in Personalized Medicine in Psychiatry

Information and communications technologies allow for the discreet monitoring, in ecological settings, of behavioral, physiological, and cognitive/emotional factors that are collected using sensors, biosensors, and self-report instruments, respectively (Mohr *et al.* 2017).

Mobile Phones

Mobile phones are the most ubiquitous personal platform. Using embedded sensors and apps, such as accelerometers, geolocation, short message service, calls, and social network data, mobile phones collect behavioral information about people's habits, sleep patterns, and social interactions.

It has been demonstrated by Likamwa *et al.* (2013) that the number and length of communications, a person's locations, and app usage patterns are related to mood in nonclinical populations. In addition, mobile phones can be effectively used to deliver psychotherapeutic interventions (Mantani *et al.* 2018).

Wearable Devices

Wearable devices are sensor technologies designed to be worn on the wrist or clipped to the belt. They are generally used for specific purposes (health and fitness). These devices continuously track activities, such as the number of steps taken, miles traveled, and hours spent sleeping, including the length of REM and non-REM sleep, as well as heart rate and respiratory rate. Wearable devices record higher-quality data compared with smartphones; however, they were used by only about 20% of the U.S. population in 2018.

Electronic Medical Records

Electronic medical records (EMRs) contain a large amount of real-world patient information collected in standard clinical care. However, the clinical data included in the EMRs are usually not coded in formats that are suitable for statistical analysis (i.e., they are written in natural language that needs to be processed before analysis, and contain missing values and/or inhomogeneous set of data) (Perna *et al.* 2018). Favorably, previous literature demonstrated that the analytical techniques for extracting and coding relevant information from unstructured data (e.g., applying natural language processing tools to clinical notes) have high accuracy in terms of diagnostic classification of mood episodes (Castro *et al.* 2015). However, a recent systematic review on machine learning and natural language processing in mental health (Le Glaz *et al.* 2021) suggested that these techniques tend to confirm clinical hypotheses rather than aid in developing new information.

Technology-Based Ecological Momentary Assessment

Another promising contributor to PMIP is the potential of new digital technologies for psychiatry assessments and interventions. The technology-based *ecological momentary assessment* (EMA) is a strategy for assessing the psychopathological condition of a patient in naturalistic settings, allowing for a real-time collection of cognitive,

emotional, and behavioral data that can be stored and sent to clinicians and/or researchers. EMA-specific items, filled in several times a day, prompted by a scheduled signal from the device or around stressful events, include symptoms such as depressed mood, anxiety, and suicidal thoughts.

Compared with traditional clinical rating scales, EMA has many advantages. It allows for real time data collection (minimizing recall bias), analyzes changes that occur over time, and takes place in the individual's natural environment.

The apps for self-monitoring have prompted promising research on major depressive disorder (MDD) and suicidal behavior. EMA symptoms monitored in depressed patients were highly correlated with baseline Hamilton Rating Scale for Depression score (Hung *et al.* 2016) and significantly predicted response at week 6 after augmentation with quetiapine extended-release (XR) in MDD patients who had not responded to antidepressant treatment alone (Schaffer *et al.* 2013).

Correspondingly, real-time monitoring of suicidal thoughts via mobile EMA captures transient instances of suicidal ideation that may not be detected by traditional, retrospective, self-report measures. Detection of such transient instances helps identify subgroups of patients at risk for suicide who might otherwise have been missed (Gratch *et al.* 2021).

Monitoring of Physiological Parameters

The information collected by the EMA can be integrated with data obtained from wearable biosensors, which monitor physiological parameters throughout the day (Marzano *et al.* 2015), and smartphone-embedded sensors, which provide data on patients' behaviors and habits (Mohr *et al.* 2017). Thus, a panel of information that has the potential to revolutionize the traditional assessments of psychiatric illnesses is produced.

Computational Approach to the Complexity of Psychiatry

Recent developments in technology and data analysis methods may help overcome the complexity inherent in psychiatric practice. In machine learning, computer algorithms learn the general principles underlying a series of observations (training data) and successively apply such principles to never-before-seen cases without human guidance. The advantage of machine learning in PMIP is its ability to integrate large sets of variables and capture complex dependencies between variables.

Machine learning algorithms can be divided into three categories: supervised, unsupervised, and reinforcement learning models (Galatzer-Levy *et al.* 2018). *Supervised* models learn from a known, labeled training dataset to predict new output values. Its algorithms are designed to predict discrete (e.g., improvement or remission) or continuous (e.g., symptom severity) outcomes from clinical, genetic, or brain function data. *Unsupervised* models use unclassified/unlabeled training information and draw inferences from datasets to discover unknown statistical configurations (e.g., how variables cluster together or relate to one another) without reference to a specific and predefined outcome. *Reinforcement learning* models determine the optimal behavior to obtain the maximum reward through continuous interaction with the environment via a process similar to a trial-and-error search.

Personalized Prescribing in Psychiatry

PMIP aims to develop treatment according to the patient's specific characteristics by integrating information from clinical features, biomarkers, genetic factors, and environmental influences. In particular, recent advances in genetics technology have promised to transform the way drug treatments are prescribed to patients. The premise of genetically guided prescribing (pharmacogenetics) is to match the drug's pharmacological profile to the patient's genetic profile. Although the genetics-based prediction of the pharmacodynamic activity of psychiatric drugs is challenging because of the aforementioned diagnostic difficulties, the genetic factors that influence the pharmacokinetics of common psychiatric drugs are well known. Most psychotropic drugs are metabolized in the liver by enzymes of the cytochrome P450 (CYP) family, with their genetic variation significantly contributing to total drug exposure. Nevertheless, despite the enthusiasm due to the exponential reduction in genotyping costs (a polygene variant panel can now be performed for less than 100 U.S. dollars), routine use of pharmacogenetics prior to drug initiation is not yet supported by the empirical literature. Currently, psychiatric pharmacogenetics is considered the standard of care only for *HLA-B*15:02* genotyping before the initiation of carbamazepine in patients with Asian ancestry to predict the risk of Stevens-Johnson syndrome/toxic epidermal necrolysis emergence (Sung *et al.* 2020).

In the next section, we report on some of the main findings of the PMIP approach to treatment of psychiatric disorders.

Application of PMIP in Treatment of Psychiatric Disorders

Predicting Antidepressant Response in Major Depressive Disorder

MDD is a common, debilitating, and costly disease and is the subject of in-depth study using the PMIP approach. Despite the large number of antidepressant drugs (ADs) available, fewer than half of patients with MDD achieve remission of symptoms with their first prescribed antidepressant, and almost one-third fail to achieve remission even after four consecutive treatment trials (Warden *et al.* 2007), with a very negative impact on the severity and chronicity of the MDD course (Akechi *et al.* 2019).

PMIP, which develops therapeutic interventions according to the unique profile of each patient by integrating information from clinical features, biomarkers, and environmental factors, can be a crucial strategy for improving pharmacological responses in MDD.

Sociodemographic and Clinical Factors

Numerous studies have evaluated whether the variables that can be easily obtained in clinical practice through clinical interviews can be used to personalize the pharmacological treatment of MDD. The narrative review conducted by Perna and coworkers concluded that neither sociodemographic nor clinical variables, when considered independently, were reliable factors for the selection of a specific antidepressant class or compound in clinical practice (Perna *et al.* 2020a). Rather, the poor outcomes of the whole group of antidepressants were associated with low socioeconomic status, African genetic ancestry, overweight/obesity, very severe pretreatment depressive symptoms, depression with melancholic symptoms, and significant anxiety symptoms (Perna *et al.* 2020a).

Childhood maltreatment, which involves acts of commission or omission by parents or caregivers resulting in potential harm to the child's mental and physical health, is a further variable that can be obtained through clinical interviews. A large body of evidence (Lippard and Nemeroff 2020) clearly indicates that a history of childhood maltreatment is a predictor of poor outcome for all treatments for MDD (i.e., psychological therapy, antidepressants, or combined treatments). However, a recent systematic review that performed head-to-head comparisons of antidepressant treatments among MDD patients with or without a reported history of childhood maltreatment did not draw reliable conclusions on the possibility of childhood maltreatment assessment being used for selecting specific antidepressant classes or compounds because of the scarcity and heterogeneity of the included studies (Perna *et al.* 2021).

Increasing evidence has supported the relevance of inflammation in MDD, as suggested by increased peripheral levels of proinflammatory cytokines, chemokines, and C-reactive protein (Caldirola *et al.* 2021). In general, depressed patients with elevated inflammatory markers exhibit a poorer response to antidepressant treatment. A recent systematic review and meta-analysis (Liu *et al.* 2020) indicated that patients with MDD who exhibited a better response to antidepressant treatment had lower baseline interleukin-8 levels compared with nonresponders.

Pharmacogenetics

Single-nucleotide polymorphisms (SNPs) (i.e., single base-pair changes in the DNA sequence), which explain about 42% of the variance in antidepressant response (Tansey *et al.* 2013), could be utilized to personalize treatment choices. Several studies analyzed candidate genes (i.e., those assumed to play a role in the pharmacodynamics and pharmacokinetics of ADs). However, analysis of the polymorphisms of pharmacodynamic candidate genes involved in serotonin synaptic transmission (*SLC6A4*, *HTR2A*), neurotrophic activity (brain-derived neurotrophic factor [*BDNF*]), and catechol-O-methyltransferase (*COMT*) modulation revealed a small and poorly reproducible predictivity of AD response in patients with MDD (Fabbri *et al.* 2020). Recently, the rs1800532 polymorphism of the serotonin transporter gene (*SLC6A4*) was found to be correlated with both suicide vulnerability and poor response to lithium and clozapine, the only documented agents with antisuicidal properties (De Berardis *et al.* 2021).

Polymorphisms in pharmacokinetic genes responsible for antidepressant metabolism (*CYP2D6* and *CYP2C19*) have been found to affect the function of the corresponding enzymes, and a recent systematic review demonstrated that *CYP2D6* and *CYP2C19* pharmacogenetic testing may predict response to antidepressants in specific individuals; however, whether this will translate to improved or safer clinical outcomes remains unclear (Smith and Nemeroff 2020).

Furthermore, it is still debated whether genetic testing should be limited to patients exhibiting treatment unresponsiveness/sensitivity or whether the benefit

would be most marked if testing is conducted before the initiation of the first antidepressant (Zeier *et al.* 2018).

Genome-wide association studies (GWAS) compare the frequencies of SNPs between cases and controls to identify variants associated with the trait of interest. In general, GWAS have failed to identify polymorphisms associated with AD response in patients with MDD (Smith and Nemeroff 2020). (For a more detailed review, see Chapter 6, "Pharmacokinetics, Pharmacodynamics, and Pharmacogenomics," in this textbook).

Because genetic studies thus far have returned results with limited clinical utility, it has been proposed that gene-by-environment interplay may be a factor influencing not only pathophysiology but also treatment response. *Epigenetics* refers to the molecular mechanisms that regulate gene expression in response to the environment without modification in the underlying DNA sequence. DNA methylation, the most stable type of epigenetic mechanism, consists in the addition of a methyl (CH_3) group to the carbon-5 of the cytosine moiety in the DNA sequence, generating the modified nucleotide 5-methylcytosine (5mC), which is involved in gene silencing. Two other major epigenetic mechanisms are posttranslational histone modification (which controls chromatin condensation and, by this mechanism, regulates gene expression) and regulation by noncoding RNA, particularly microRNAs.

Some studies suggest that antidepressants, at least partially, act by altering or even reversing epigenetic modifications and that the methylation status of some genes could predict the response to AD treatment in patients with MDD (Czarny *et al.* 2021). Specifically, *SLC6A4* (coding for the serotonin transporter) promoter hypomethylation has been linked with diminished response to escitalopram (Domschke *et al.* 2014) and with diminished dimensional and categorical response to SSRIs (Schiele *et al.* 2021). Of note, hypermethylation of the *SLC6A4* promoter has been associated with improved response to selective serotonin reuptake inhibitors (SSRIs) such as paroxetine and fluvoxamine (Okada *et al.* 2014). However, because the data obtained in retrospective studies do not allow for differentiation between preexisting differences in DNA methylation (due to heredity and/or environmental factors) and those induced by the treatments, investigation with longitudinal designs is required.

Although it seems that the results of the remaining omics platforms (transcriptomics, proteomics, and metabolomics) indicate the possibility of developing actionable biomarkers for the selection of AD for MDD treatment, studies that support their application in clinical practice are lacking.

Brain Imaging

Structural and functional brain imaging has been explored as a putative index of treatment response in MDD. A recent systematic review (Enneking *et al.* 2020) demonstrated that larger pretreatment anterior cingulate cortex and hippocampal volumes are correlated with response to ADs and found that machine learning approaches based on pretreatment whole-brain patterns exhibited accuracies of 64%-90% in predicting AD response at the individual MDD patient level. Furthermore, altered connectivity of cingulum cingulate and stria terminalis tracts is predictive of remission after 8 weeks of treatment with escitalopram, sertraline, or venlafaxine (Porcu *et al.* 2018). However, despite the number of neuroimaging studies conducted on the AD response in MDD, the results are too inconsistent to produce predictors available in clinical practice.

Electroencephalographic Biomarkers

In comparison with brain imaging techniques, electroencephalography (EEG) is potentially more cost-effective and can be more feasibly and safely implemented in different clinical settings. Quantitative electroencephalography (QEEG) using standardized and reproducible mathematical algorithms enables the measurement of the alpha, theta, beta, and gamma patterns of rhythmic electrical activity and evoked potentials (i.e., the average brain response to a repeated stimulus). However, although a recent meta-analysis (Widge *et al.* 2019) concluded that QEEG was not clinically reliable for predicting depression treatment response owing to the methodological limitations of the then-existing studies, more recent publications are very promising indeed (Liu *et al.* 2020; Zhdanov *et al.* 2020).

Predicting Lithium Response in Bipolar Disorder

Bipolar disorder (BD) is a severe illness characterized by pathological mood swings, from depressive episodes to periods of elevated/irritable mood defining mania (BD type I) or hypomania (BD type II) episodes. Additionally, some patients with BD may experience mixed episodes in which various combinations of depressive and manic symptoms occur. BD treatment aims to stabilize mood and prevent future depressive and manic episodes. Lithium is the mainstay treatment for preventing mood relapses of any polarity and suicidal behaviors, and for treating acute manic episodes in patients with BD. However, among patients receiving lithium for at least 2 years, three subgroups have been consistently identified--complete responders, partial responders, and nonresponders--with about one-third of patients belonging to each group. For patients in the second and third subgroups, antipsychotics and antidepressants may be necessary as adjunctive therapy to attain euthymia (Vieta *et al.* 2011).

Sociodemographic and Clinical Predictors of Lithium Response

A recent systematic review and meta-analysis of 71 studies (Hui *et al.* 2019) identified six clinical predictors of good response to lithium therapy in BD: a mania-depression-interval course sequence, absence of rapid cycling and psychotic symptoms, family history of BD, shorter illness duration prior to lithium being prescribed, and later age at onset.

A further systematic review, including 34 studies (from 31 independent datasets) published between 1991 and 2018 (Grillault Laroche *et al.* 2020), reported sociodemographic and/or clinical variables associated with treatment response and/or with illness outcome during long-term lithium treatment ([?] 6 months). When the analysis of results was restricted to the 11 good-or borderline-good-quality studies, only the higher lifetime number of hospitalizations remained associated with a poor outcome for lithium prophylaxis, while no predictors of good outcome were identified.

The Pharmacogenomics of Bipolar Disorder (PGBD) study was a recent 11-site prospective trial designed to identify predictors of lithium response in patients with BD type I followed for up to 2 years (Lin *et al.* 2021). Significant clinical predictors of treatment failure included baseline anxiety symptoms, functional impairments, adverse life events, history of migraine, suicidal ideation/suicide attempts, and mixed episodes, as well as a chronic course of illness. Unlike the above-reported reviews, the

PGBD study found no evidence for an association of lithium treatment response with age at onset, number of hospitalizations, or rapid cycling (Lin *et al.* 2021).

Pharmacogenomics of Lithium Response in Bipolar Disorder

The candidate gene approach selects a putative gene based on its relevance in the postulated mechanism of the pathophysiology of the investigated disease and/or pharmacological response. None of the studies that explored a candidate genomic region evidenced a linkage between genetic markers at these loci and lithium response.

The lack of replicability of linkage studies that performed scans of the entire genome suggests that no major genes are involved in lithium response. Similarly, the candidate gene association studies on lithium response could not provide replicable associations between candidate genes or variants and lithium response (Senner *et al.* 2021).

Unlike candidate gene studies, GWAS are not based on a priori hypotheses. Some of the GWAS, which try to identify common genetic variants with small effect sizes throughout the genome in large populations that include cases and controls, have reported SNPs that showed significant associations with response to lithium. A recent study (Vecera *et al.* 2021) reviewed six GWAS on genetic variations related to lithium response and side effects in patients with BD. Variants associated with lithium response were found on genes *GADL1* and *GRIA2* regulating the glutamate system, which has been extensively implicated in mood disorder pathophysiology. In addition, SNPs on the spectrin domains 1 gene (*SESTD1*), which encodes a synaptic protein that directly binds to phospholipids, may account for lithium's ability to permeate cell membranes and mediate autoimmune and renal effects.

From a pharmaco-epigenetic point of view, increasing data have shown not only that antidepressants, mood stabilizers (anticonvulsants and lithium), and atypical antipsychotics modulate DNA methylation at promoters of genes involved in their targeted pathways but also that the observed effects can be associated with the pharmacological response. The first genome-wide association study of DNA methylation profiles in patients with BD, selected for their level of response to long-term treatment with lithium, identified seven differentially methylated regions with good discriminatory power between excellent response and nonresponse to lithium in patients with BD type I (Marie-Claire *et al.* 2020). However, it cannot be concluded that the epigenetic changes observed in the presence of a given drug are purely the effect of the drug and not the sum of this effect and other environmental factors that could modify DNA methylation. Further prospective studies that include environmental factors during the illness as well as treatment are needed to understand the potential use of DNA methylation as a predictive biomarker.

In conclusion, although GWAS have provided a powerful approach to addressing the main limitations of studies on candidate genes, replication of results in larger cohorts and different populations of patients with BD is needed.

Neuroimaging

A few longitudinal structural neuroimaging studies examined whether gray matter changes during lithium treatment correlate with lithium response. A positive clinical response in medication-naive patients with BD was associated with persistently increased cerebral gray matter volume throughout the 16-week lithium treatment (Lyoo *et al.* 2010). Similarly, a 4-week longitudinal study showed that BD patients

with a manic episode who responded to lithium had an increased prefrontal gray matter volume compared with those who did not respond (Moore *et al.* 2009). The relationship between response to lithium treatment in BD and task-based brain activation changes on functional MRI (fMRI) has been only sparsely investigated. A pilot study found greater activation to an emotional faces task in the prefrontal cortex and reduced activation in limbic regions in long-term lithium responders than in nonresponders (Rootes-Murdy *et al.* 2019).

Another fMRI measure, resting-state functional connectivity (RSFC), identifies functional connections between brain regions (not necessarily implying anatomical connectivity). Taylor *et al.* (2021) have reviewed studies on RSFC biomarkers of treatment response in mood disorders, including BD. Although cortico-limbic connectivity is implicated across studies, no single biomarker replicated in multiple independent datasets has been found.

Electroencephalographic Biomarkers

Some studies analyzing the relationship between EEG and lithium response suggested that patients with electroencephalographic abnormalities were more likely to respond to valproate than lithium (Ikeda *et al.* 2002). Other studies investigated the event-related potentials as possible predictors of lithium response. In both cases, the few studies and the small patient populations investigated prevented the possibility of drawing any firm conclusions (Tighe *et al.* 2011).

Predicting Antipsychotic Drug Response in First Episode of Psychosis

Schizophrenia is a severe disorder presenting psychotic symptoms, such as hallucinations and delusions, and cognitive deficits. Because attaining a clinical and functional improvement in patients in their first episode of psychosis (FEP) is critical to producing a positive long-term illness outcome, identifying factors predicting treatment response in the early phase of the disease is the focus of much research.

Long-term use of atypical antipsychotics is the first-line treatment in schizophrenia. However, even during the FEP, when the response to antipsychotics tends to be greater, up to one-quarter of patients show persisting symptoms of schizophrenia (Schennach *et al.* 2012). Clozapine is effective in patients who have not responded to other antipsychotics but carries the risk of serious side effects and requires regular blood monitoring; thus, identifying predictive biomarkers of clozapine response may aid in the early initiation of clozapine treatment.

Sociodemographic and Clinical Predictors of Antipsychotic Response in FEP

In patients experiencing their FEP, gender and marital status are controversial predictors of antipsychotic response (Bozzatello *et al.* 2019), while poor premorbid adjustment and lower educational level predict a worse drug treatment response. Clinical predictors of treatment resistance and poor outcome in adults and children with FEP include higher severity of negative symptoms at baseline (Demjaha *et al.* 2017; Downs *et al.* 2019) and comorbidity with substance use disorders--in particular, cannabis (Pelayo-Teran *et al.* 2014).

A 10-year longitudinal study (Demjaha *et al.* 2017) revealed that in the great majority of patients with treatment-resistant schizophrenia, the resistance is present from the illness onset. Negative symptoms, younger age at onset, and longer duration of untreated psychosis predicted treatment resistance.

In a recent review of prospective longitudinal studies (Smart *et al.* 2021), out of the seven studies that tested the age at onset as a response predictor, six reported that younger age at onset predicted treatment-resistant FEP.

Pharmacogenetics

Antipsychotics mainly bind to dopamine D$_2$ and serotonin 5-HT$_{2A}$ receptors. However, studies linking genetic variation in *DRD2* to antipsychotic efficacy or adverse reactions have been inconsistent (Yoshida and Muller 2020). Several studies reported that the serotonin 5-HT$_{1A}$ receptor gene (*HTR1A*) polymorphism rs6295 was significantly associated with a clinical improvement with second-generation antipsychotics, but further studies using larger sample populations are required to confirm this effect (Takekita *et al.* 2016). Some studies support the involvement of glutamate gene polymorphisms in response to risperidone in FEP patients (Stevenson *et al.* 2016) as well as in an early (2-week) response to risperidone, which is a good indicator of subsequent pharmacological outcome (Sacchetti *et al.* 2017). Overall, evidence pointed to a role for the serotonin (5-HT_{2A} and 5-HT_{3A}; *HTR2A* and *HTR3A*), dopamine (D_2; *DRD2*), and glutamate system (glycine transporter 1; *SLC6A9*) genetic variants in clozapine response (Taylor *et al.* 2017; Zai *et al.* 2018).

Although some genetic tests (e.g., response to clozapine and risperidone) are commercially available, their clinical validity and utility have not been systematically evaluated or reported in published randomized clinical trials.

It is known that antipsychotics can induce the alteration of the methylation status of genes coding for their targeted pathways. Some methylation patterns existing before the use of antipsychotics can affect the efficacy of these medications (Tang *et al.* 2014; Zai *et al.* 2018), but our understanding of their contributions in schizophrenia is still in its infancy.

Neuroimaging

Structural neuroimaging studies have indicated that a reduced gyrification (a marker of normal cortical development) across multiple brain regions (Palaniyappan *et al.* 2013) is associated with poor response to antipsychotic treatment in patients with FEP. In contrast, a thinner cortex at baseline in antipsychotic-naive FEP patients predicted more robust clinical and cognitive improvement with clozapine and risperidone (Molina *et al.* 2014). In addition, drug-naive or minimally treated FEP patients with a larger pituitary volume at baseline showed less improvement in positive and overall psychotic symptoms during the initial 12 weeks of treatment with quetiapine (Garner *et al.* 2009).

Prospective studies have found that greater prefrontal cortical volumes prior to antipsychotic treatment are associated with a better response to clozapine. Accordingly, responders to clozapine had higher baseline perfusion and metabolic rate in the dorsolateral prefrontal cortex compared with the nonresponder group (Rodriguez *et al.* 1997; reported in Samanaite *et al.* 2018). However, it is unclear whether prefrontal structural integrity/activity may be specifically predictive of clozapine response or is a nonspecific prognostic factor.

RSFC showed that in medication-naive patients with FEP, greater default mode network (DMN) connectivity indices were associated with a more favorable subsequent response to antipsychotic treatment (Maximo *et al.* 2021). The DMN, which includes brain areas that are functionally and structurally connected (portions of frontal and posterior midline regions and the inferior parietal lobe), is a brain network suppressed during goal-directed activity and active during rest. Because the strength of connectivity within the DMN is thought to reflect the integrity of white matter tracts that connect these regions, this finding adds to the previous literature supporting the concept that white matter integrity has potential utility in predicting antipsychotic treatment response (Crossley *et al.* 2017)

Unfortunately, the paucity of longitudinal neuroimaging studies in this area makes it impossible to draw conclusions about their predictive value in clinical practice.

Electroencephalographic Biomarkers

A few studies have investigated electrographic baseline indices as possible predictors of response to antipsychotic drugs. A greater amount of fast activity has been described in patients who were responsive to antipsychotics compared with those who were resistant, while a predominance of alpha activity has been found in patients with a poor response to antipsychotic drugs. However, the ability of these indices to predict clinical response in individual subjects was not demonstrated (Mucci *et al.* 2006).

Application of PMIP in Other Disorders

Posttraumatic Stress Disorder

PTSD develops in some individuals after exposure to a traumatic event. The main clinical features of PTSD are the reexperiencing of the event, avoidance of trauma-related triggers, hyperarousal, and negative mood/cognitions. Currently, studies of personalized approaches to the treatment of PTSD are limited to psychotherapeutic interventions (Szeszko and Yehuda 2019), and no investigations on prediction of response to pharmacological treatments are available.

Anxiety Disorders

In the last two decades, several studies have investigated the response prediction to current pharmacological treatments in the three most common and debilitating anxiety disorders, namely, panic disorder, generalized anxiety disorder, and social anxiety disorder.

Unfortunately, investigation of clinical characteristics and neurobiological, genetic, and epigenetic markers in these disorders has thus far demonstrated only a marginal role in predicting treatment response and does not appear to be translatable to clinical practice (Perna *et al.* 2020b).

Recently, a first step toward personalized therapy for panic disorder, based on some phenomenological profiles (i.e., respiratory, cardiac, vestibular, and derealization/depersonalization), has been proposed (Caldirola and Perna 2019).

Conclusion and Future Directions

The aims of the personalized medicine approach are to achieve an accurate diagnosis and select the best therapeutic option for each person by integrating clinical, biological, and environmental factors. The development of personalized medicine in psychiatry is difficult because of the intrinsic complexity of psychiatric diseases. PMIP is based on the collection of very-large-scale data (big data) that are analyzed using advanced computational tool kits capable of making a prediction from such information. Information and communications technologies, such as mobile phones and wearable devices, allow for discreet monitoring of behavioral, physiological, and cognitive/emotional factors in ecological settings. Thus far, data obtained from clinical assessment, omics platforms, pharmacogenomics, neuroimaging, and EEG do not support the application of the PMIP approach in clinical practice.

Since the completion of the Human Genome Project in 2003, progress on the predictability of pharmacological treatment response and side effects based on patients' genetic signatures has been much slower than initially expected. Such a delay is partially due to the involvement of multiple genes in a patient's response to drugs, making it unlikely that a simple pathway from the gene to the pharmacological response will be found. This drawback prompted the development of new methodological approaches that take into account the complex polygenic architecture of antidepressant efficacy. For example, polygenic risk may be well utilized to estimate the multi-allelic contribution to antidepressant efficacy, providing an estimation of the individual genetic risk of developing a specific trait (e.g., antidepressant response).

International collaborations to increase sample size and the high-throughput nature of omics technologies, as well as recent developments in machine learning (time-series techniques, methods based on Bayesian hierarchical models, and matrix factorization techniques), promise to achieve the final goal of developing an individual-level personalized psychiatry. The ultimate frontier of PMIP could be cell culture models, in which psychiatric disorders are manifestations of the donor's individual genetics and environmental interaction.

The generation of induced pluripotent stem cells (iPSC) from patients with a variety of single-gene or complex-inheritance diseases provides an unprecedented opportunity to recapitulate the pathological human tissue formation in vitro, thereby enabling disease investigation and drug development.

CHAPTER 9

Machine Learning in Psychopharmacology

Isaac R. Galatzer-Levy, Ph.D.
Anzar Abbas, Ph.D.

Psychopharmacology focuses on mechanistic explanations and subsequent interventional approaches to psychiatric illness (Wang and Krystal 2014). Consistent with pharmacology more broadly, modern psychopharmacology is increasingly focused on targeted and personalized treatment options (Chekroud *et al.* 2017; Stahl 2008). With mechanistic explanations of psychiatric illness evolving to take into account expanding layers of research (i.e., genomics, epigenomics, proteomics, neuroimaging, electrophysiology), the subsequent interventional approaches are subject to further personalization through development of more sensitive, objective, and patient-specific measurements of mental health and illness (Galatzer-Levy and Galatzer-Levy 2007; Insel *et al.* 2010; Wang and Krystal 2014). To achieve this, there is an emerging reliance on advanced computational methods grounded in machine learning. In this chapter, we provide a brief summary of statistical approaches in psychopharmacology, summarize general machine learning approaches and the problems in psychopharmacology they are well suited to address, and provide examples of where such approaches have been useful in clinical research and patient care.

History of Statistical Approaches in Psychopharmacology

Classical Statistical Approaches in Psychopharmacology

The 1970s and 1980s saw a movement in psychiatric diagnosis away from theoretical study of mental illness and toward an increasingly scientific approach grounded in

observable phenomena. This shift to the use of scientific methods eventually led to a major revision of DSM, in which diagnosis became grounded in observable symptomatology (Galatzer-Levy and Galatzer-Levy 2007), as research on psychiatric illness sought to develop a methodology that would allow scientists to carefully separate relevant symptoms and direct effects of treatment from the noise of patients' interpersonal and environmental surroundings.

In the context of development of novel treatments, the focus shifted to outcome measures that would facilitate statistical hypothesis testing as a methodology to determine treatment efficacy. Such testing allowed researchers to arrive at, for the first time, a common understanding of psychiatric treatment effects through "standardized" research methodologies, measures, and mathematical language. This shared understanding laid the groundwork for the modern clinical trial in psychiatry.

Clinical trials largely follow the methodology proposed by Ronald Fisher (Stigler 1986), in which the impact of an intervention is assessed as the covariance between the independent and dependent variables (Fisher 1921). Analysis of variance (ANOVA), also introduced by Fisher, allows researchers to formally compare the average effects of an independent variable on a dependent variable and provide a probabilistic estimate that the observed difference in conditions is statistically meaningful. With the emergence of standardized outcome measures in psychiatry, the classical clinical trial design could now be applied to evaluate novel interventional compounds in a manner that had not been possible before.

Limitations of Classical Statistical Approaches in Psychopharmacology

Fisher's approach, which also introduced common statistical concepts such as a *P* values, came with two caveats, with both having considerable effects on the utility of this approach in psychopharmacology. First, for Fisher's statistical approach to work, all variables other than the independent and dependent variables must be held constant. Focusing on a single main effect is particularly challenging in psychopharmacology, which aims to demonstrate *effectiveness* of treatment in messy real-world contexts over efficacy in tightly controlled scenarios (Goldberg and Stahl 2021). Second, Fisher's approach only aimed to test (i.e., confirm or reject) a *null hypothesis* that the different experimental conditions are the same. This approach, while valuable for testing a scientific hypothesis for the first time, does not allow one to make a prediction about future events. Put another way, this means that traditional statistical approaches are well suited to rigorous testing of whether a compound had an effect on a population *over chance*, but they are not designed to make predictions on correct dose or course of treatment, which are necessary for development of personalized treatments.

Limitations of Psychiatric Nosology for Application of Statistical Approaches

Another major barrier in the development of personalized treatments in psychopharmacology is the existing psychiatric nosology, which is neither personal nor specific. The measurement scheme underlying DSM diagnoses has limitations that preclude it from being a viable tool to assess sensitive and specific effects of treatment (Galatzer-Levy and Bryant 2013). First, the summation of individual symptom measurements to determine whether a patient's presentation meets criteria for a particular disorder assumes that individual symptoms are equally weighted, but there is strong evidence against this being the case. Second, DSM intentionally avoids mechanistic explanations of psychiatric illness. The fact that there is no evidence that symptoms are causally related to one another places any method that combines them on shaky logical ground. Third, given that some but not all symptom criteria are required to be met, a pool of individuals who share a diagnosis may be shockingly heterogeneous in their symptom presentation. Simultaneously, many diagnoses are often comorbid and responsive to similar treatments, casting doubt on the discrete nature of psychiatric illness classifications. The lack of specificity in outcome definitions has consequences for psychopharmacology. Targeted treatments are more likely to succeed when they are focused on individual symptoms (e.g., motor functioning, circadian rhythm, cognition) rather than on disease classifications (e.g., major depressive disorder, PTSD, autism spectrum disorder).

In short, modern psychopharmacology is presented with two fundamental problems. First, the mathematical approach to making decisions about cause and effect does not allow for the diversity of inputs necessary for prediction that enables personalization. Second, outcome measures in psychiatry are not sensitive enough to measure the current class of treatment compounds, which are targeted toward neurological pathways with broad downstream effects. Machine learning introduces potential solutions to both of these fundamental problems.

Machine Learning and Its Applications in Personalized Psychopharmacology

Machine learning broadly refers to the practice of learning patterns from data to improve performance and make predictions (Galatzer-Levy 2014). Machine learning algorithms attempt to identify complex relationships between variables. Personalized medicine has three primary classes of problems (Statnikov *et al.* 2011):

1. Given a patient, can we predict disease type or subtype?

2. Given a patient, can we predict the correct treatment?
3. Given a patient, can we predict the correct dosage of treatment?

Rather than exhaustively summarizing machine learning methods, we summarize approaches to address each of the questions above as they relate to psychopharmacological drug development and utilization.

Can We Predict Disease Type or Subtype?

DSM provides a framework in which symptoms cluster into disorders or subtypes of disorders based on a set of decision rules and cutoff points. The DSM approach can be considered an algorithmic approach to classification. In this subsection, we discuss empirical approaches to defining clinical populations/subpopulations.

Unsupervised Learning

Unsupervised machine learning refers to a class of algorithms that draw inferences about the relationship between variables in the absence of a label (Galatzer-Levy and Galatzer-Levy 2007; Bernardo and Smith 2001). As a general example, unsupervised machine learning could be used to group individuals according to their level of severity on one or more clinical indicators. Similarly, researchers can cluster patients on the basis of behavioral characteristics and presentation of symptoms (Scholz 2014). Importantly, they can do this without needing an a priori definition of a diagnostic status. Unsupervised machine learning models allow for dimensionality reduction (Barlow 1989), which is useful in psychiatry, where high-dimensional data from behavioral quantifications and symptom measurements must be evaluated simultaneously. Ultimately, unsupervised machine learning allows for the clustering of populations into subgroups without the need for arbitrary decision rules and cutoff points.

One commonly used approach is *mixture modeling*, which relies on identifying *latent* (or not directly observable) populations by identifying underlying mixture distributions (Mori *et al.* 2020). The mathematical approach to clustering in this way does not differ significantly from feature reduction approaches. However, instead of asking how variables cluster together within people, one seeks to identify how people cluster together on variables (Muthen and Muthen 2000). Examples of this include empirical identification of disease subgroups in major depressive disorder (Ulbricht *et al.* 2018), PTSD (Campbell *et al.* 2020), and autism spectrum disorder (Dekker *et al.* 2021). This technique is not limited to the clustering of symptom profiles alone. Researchers can identify symptom profiles that cluster with comorbidities, functional impairment, and population-level characteristics. Empirical identification of these subtypes allows for development and facilitation of personalized treatment (Grant *et al.* 2020).

Graphical/Network Models

A limitation of models that include complex dependencies across a large number of variables is that they are difficult to interpret. Graphical models provide a framework for representing multidimensional relationships in two-dimensional space to aid in interpretation and, in some instances, hypothesis testing (Muthen 2004). Although the mathematical basis of such models may vary (most commonly between Bayesian networks and Markov random fields), the underlying concepts are similar (Galatzer-Levy *et al.* 2017a). Researchers can derive the structure of multiple related variables by algorithmically testing conditional dependencies between all variables of the model. Graph models are increasingly utilized in stress pathology research to better understand how multiple relevant dimensions relate to one another. A number of recent publications have examined how certain symptoms such as complicated grief (Malgaroli *et al.* 2022), comorbid depression and obsessive-compulsive behavior (McNally *et al.* 2017), and PTSD (Galatzer-Levy *et al.* 2017b) relate causally.

Supervised Learning

Supervised machine learning is a class of data modeling that is concerned with the development of algorithms that can learn a function applied to the data that optimally predicts an outcome (Singh *et al.* 2016). These models fall into two classes: *classification models*, which attempt to predict a categorical outcome (e.g., healthy vs. ill based on behavioral and symptom features), and *regression models*, which attempt to predict a continuous outcome (e.g., symptom severity reduction in response to treatment). Classification models have particular relevance to predicting disease type or subtype. Their benefit is similar to that of unsupervised machine learning models in that they

do not require arbitrary cutoff points or thresholds to predict--using a set of features (i.e., symptoms, observed behavior)--a diagnosis. They are distinct from unsupervised models in that the relationship between the features and the ultimate classification (i.e., the diagnosis) is *learned* from existing data.

Can We Predict the Correct Treatment?

As previously discussed, traditional null hypothesis testing is not designed to make predictions. Rather, the goal of those statistical methods is to establish association to confirm or disconfirm a scientific hypothesis. While this is of great value, the next logical question is how to apply the field's accumulated knowledge to make an accurate clinical decision about a specific patient (Bzdok *et al.* 2021).

Unsupervised Learning

Often, the most relevant patient characteristic is their pattern of response to treatment. Traditional approaches to defining meaningful change over time (e.g., 30% reduction in symptoms, change in diagnostic status) lack a clear empirical basis. The use of latent variable approaches to characterize individuals within a population that are similar to one another in their level of symptom severity (intercept) and change over time (slope) is commonly known as *latent growth mixture modeling* (Jung and Wickrama 2008). Latent growth mixture modeling has relevant applications to treatment personalization in psychopharmacology. By identifying individuals' predictive profile in response to varied treatments, clinicians can identify individuals more likely to respond to specific treatments, such as different classes or combinations of antidepressants (Stulz *et al.* 2010).

Graphical/Network Models

After graphical models are identified, they can be used for purposes beyond description of observed patient characteristics, such as to better understand treatments that can be utilized. After determining the relationships between variables in a graph, researchers can conduct experiments to set the value of a particular variable to determine its downstream effects on other variables of interest (Statnikov *et al.* 2011). For example, a researcher who has derived a graphical model of a gene expression network may want to know how downstream expression patterns are affected, if at all, when they alter the value of a particular target with a drug. Such an experiment allows the researcher to develop hypotheses on drug effects before collecting experimental data.

Supervised Learning

Classification machine learning models also have particular relevance to prediction of correct treatment. Various approaches are used to identify and validate complex dependencies between variables using Boolean logic (AND, OR, NOT), as well as absolute conditionality (IF, THEN, ELSE) and conditional probabilities (probability of x given y). Because the relationships between variables may be nonlinear, these methods utilize computational optimization methods to identify models that are dependent on more variables than traditional statistics would allow (Kotsiantis *et al.* 2007). Once a model has been identified that combines variables to predict, for example, a treatment expected to be effective, that model can be applied to new data to make a prediction about a new case. Such a model could be embedded in software, and clinicians could enter those variables and receive a prediction of the kind of treatment most likely to be successful.

Can We Predict the Correct Dosage of Treatment?

Supervised Learning

Thus far, we have discussed the use of classification models in identifying patient subtypes and predicting effective treatment regimens. Regression models, which are another form of supervised models, have particular relevance in the prediction of dosage given their ability to make a prediction based on continuous variables rather than discrete or binary variables.

In theory, all patients in a population should demonstrate uniform treatment effects given random variability around the average response. However, multiple known and hidden variables impact the relationship between outcomes and the influencing variables. To effectively dose treatment, researchers must be capable of accurately predicting response to treatment, because these influencing variables (and likely several more) vary across the population. In psychiatry, this is often a trial-and-error approach involving one or more medications to optimize for therapeutic effect while minimizing side-effect profiles. The goal of a regression model is the same as the goal of the treating clinician: to make an accurate prediction of the degree of response based on a set of variables, both therapeutic and nontherapeutic. The challenge is the complexity of the relationships between the input variables.

Regression models can vary in complexity from linear models with simpler relationships between a few input variables to nonlinear models with complex relationships between several variables. For the latter, regularized regression techniques such as LASSO (Least Absolute Shrinkage and Selection Operator), ridge, and elastic net regression are useful because they allow the data analyst to select the preferred level of model complexity, from linear to highly nonlinear (Hans 2009). Increased complexity of a model can easily lead to overfitting. Regularized regression models include a *regularization term*, which imposes a penalty as models increase in complexity, making model fit harder to achieve as the complexity of the model increases (Xu *et al.* 2009). The coefficients of variables not relevant to the model are shrunk to minimize their impact on the model. Algorithmic identification of features that have little or no effect allows analysts to use these models for feature selection, as the most relevant variables will be selected into the model. One of the key benefits of regularized regression models is that they are highly interpretable because they provide evidence for which variables are predictive as well as the degree to which they contribute to overall predictive accuracy.

Regression-based machine learning techniques may become more relevant as the field moves toward targeting specific phenotypes or side effects typically measured using continuous indicators of functioning, such as cognitive ability, functional impairment, biological activity, or digital measurements (Abbas *et al.* 2021; Insel 2014). Such techniques have particular application in the early phases of research, including in nonclinical populations, where researchers may be interested in determining a dose-response relationship. Similarly, regression-based machine learning may become increasingly relevant as treatments aim to target specific phenotypes such as cognitive impairment, negative symptoms in schizophrenia, mood and anhedonic behavior in depression, or states of hyperarousal in anxiety disorders or PTSD (Galatzer-Levy *et al.* 2018). The use of regression models opens the door to solving multiple precision medicine problems, including individual titration of medication, prediction of high-level drug interactions, and prediction of nonclinical endpoints, all of which are relevant to psychiatry.

Limitations of Machine Learning and Its Application in Psychopharmacology

Machine learning models are powerful tools that can be used to make decisions about patient diagnosis and course of treatment. However, as with all tools available to researchers and clinicians, misapplication of those tools can lead to erroneous conclusions and dangerous consequences.

Overfitting Models

Unlike traditional statistical approaches that are meant to test specific hypotheses about the linear relationship between inputs and outcome, machine learning aims to *learn* the relationship between inputs and outcome, including the dimensional nature of the underlying relationship. As machine learning algorithms search for such relationships, they are prone to *overfit* the models, so that the solution does not generalize beyond the data that they are being trained on. There are two main solutions to this. The first is to use an additional parameter in the machine learning model we touched on earlier (i.e., the loss function). A loss function is akin to calculation of error in the model: well-fit models will demonstrate both strong model fit and low loss estimates. The second solution is to use cross-validation to determine whether the model is overfitted. Cross-validation consists of randomly splitting the training data into multiple training/testing parts. The machine learning researcher will train a model on a subset of the data they have access to (training data) and then test the model's ability to make predictions on a holdout dataset (testing data). Cross-validation involves repeating this process on multiple random splits of testing and training data so as to not overfit the model to any one iteration of the training data. This approach allows the researcher to determine whether the model was simply fit to the pool of data it was trained on or whether it generalizes across the dataset.

Bias in Machine Learning

Although randomly splitting training and testing data guards against mathematical overfitting that results in poor generalization of the model beyond the data it was trained on, this approach does not establish the generalizability and robustness of the machine learning algorithm in the real world. For example, if characteristics such as gender, race, and other key variables are not part of a dataset, any algorithm trained on that dataset will not be accurate when making predictions for a population that it was not trained on. Issues of bias are an important reason that machine learning algorithm development--within medicine and beyond--must be conducted with expertise in human subject research, because such issues cannot simply be addressed algorithmically; rather, they reflect biases inherent in the data used. It is equally important for the scientific and medical communities to understand that complex predictive models are only as relevant as the underlying data they were trained and tested on and that a concerted effort needs to be made to avoid reinforcing existing societal biases.

"Black-Box" Models and Model Updates

The term *black box* is often used to refer to the inability of a researcher or clinician to observe *how* the algorithm made a decision. It is a misnomer that the information is not available; rather, it may simply be beyond human comprehension given the dimensionality in which the relationship may have been observed by the algorithm. Increasingly, there have been attempts to add visualization layers that aid humans in interpreting complex relationships, known as *explainable artificial intelligence* (Samek *et al.* 2019). Explainable artificial intelligence is of particular importance in medicine, where both researchers' and clinicians' goals are not just to address the problem at hand but also to better understand the disease pathogenesis and to learn and expand the knowledge base in the medical community.

In certain scenarios, models are truly opaque to the researcher or clinician. With the rapid growth of interest in the use of remote monitoring in patient care and clinical research, the use of commercial devices has greatly increased. It is often assumed that all heart rate monitors embedded in wrist wearables, for example, are equivalent or that, at a minimum, the same device is consistent over time. However, sensor-based health measures, which often rely on machine learning models, are only providing estimates. Changes to the manner in which the device is used or updates to the algorithms can alter those estimates. The lack of transparency in the configuration of hardware and signal processing methods represents a significant challenge, especially in clinical research, because regulatory organizations such as the FDA have traditionally only leaned on clinical scales that are transparent, are rarely updated, and require new validation when they are updated (Benjamens *et al.* 2020).

Conclusion

The role of machine learning in psychopharmacology, psychiatry, and mental health care more broadly remains in its infancy when one considers the impact that it can have on clinical research and patient care. New approaches open up new opportunities but also introduce new risks. For psychiatry to improve patient outcomes by providing the right treatment at the right time to the right patient, it requires not only research to determine this level of personalized need but also approaches to decision making that are capable of such sophisticated calculations. Treatment development in psychopharmacology and psychiatry has relied on methods that identify average effects across heuristically defined clinical phenotypes. As the field moves toward narrow and specific phenotypes along with treatments that are matched to, and target these phenotypes, there is equally a need for data-analytic approaches to achieve these new goals. Development of such approaches represents the unrealized promise of machine learning in psychopharmacology.

CHAPTER 10

Monoamine Oxidase Inhibitors

K. Ranga Rama Krishnan, M.D.

History and Discovery

Monoamine oxidase inhibitors (MAOIs) were first identified as effective antidepressants in the late 1950s. An early report suggested that iproniazid, an antitubercular agent, had mood-elevating properties in patients who had been treated for tuberculosis (Bloch *et al.* 1954). Following these observations, two studies confirmed that iproniazid did indeed have antidepressant properties (Crane 1957; Kline 1958). Zeller (1963) showed that iproniazid caused potent inhibition of monoamine oxidase (MAO) enzymes both in vivo and in vitro in the brain. He also reported that the medication reversed some of the actions of reserpine. Because reserpine produced significant depression as a side effect, it was suggested that iproniazid might have mood-elevating properties.

The use of iproniazid soon fell into disfavor because of its significant hepatotoxicity. Other MAOIs, both hydrazine derivatives (e.g., isocarboxazid, phenylhydrazine) and nonhydrazine derivatives (e.g., tranylcypromine), were introduced. These MAOIs were not specific for any subtype of MAO enzyme, and they were irreversible inhibitors of MAO (see next section, "Monoamine Oxidase"). Their use has been somewhat limited because hypertensive crisis by the MAOIs may occur in some patients from potentiation of the pressor effects of amines (such as tyramine) in food (Blackwell *et al.* 1967).

In more recent years, there has been a resurgence of interest in the development of new MAOIs--that is, in development of MAOIs that are more selective for specific subtypes of MAO enzyme and that are reversible in nature. Reversible monoamine oxidase A (MAO-A) inhibitors, such as moclobemide, have been introduced in Europe but are not available in the United States. Newer MAOIs, such as selegiline, a monoamine oxidase B (MAO-B) inhibitor, have been introduced. Table 10-1 classifies the MAOIs by structure, selectivity, and reversibility.

Monoamine Oxidase

A and B Isoenzymes

MAO is widely distributed in mammals. Two isoenzymes, MAO-A and MAO-B, are of special interest (Cesura and Pletscher 1992). Both are present in the CNS and in some peripheral organs. For example, MAO-A is present in the liver, heart, and pancreas, and MAO-B is present in the liver, posterior pituitary, renal tubules, and endocrine pancreas (Saura *et al.* 1992). Both MAO-A and MAO-B are present in discrete cell populations within the CNS. MAO-A is present in both dopamine and norepinephrine neurons, whereas MAO-B is present to a greater extent in serotonin (5-HT)-containing neurons. Both are also present in monoaminergic neurons in various subcortical regions of the brain. Glial cells also express MAO-A and MAO-B (Cesura and Pletscher 1992).

The physiological functions of these two isoenzymes have not been fully elucidated. The main substrates for MAO-A are epinephrine, norepinephrine, and 5-HT. The main substrates for MAO-B are phenylethylamine, phenylethanolamine, tyramine, and benzylamine. dopamine and tryptamine are metabolized by both isoenzymes. The localization of the MAO subtypes does not fully correspond to the neurons containing the substrates. The reason for this discrepancy is unknown. The occurrence of the MAO-B form in 5-HT neurons may actually protect those neurons from amines (other than 5-HT) that could be toxic to them (Cesura and Pletscher 1992).

The primary structures of MAO-A and MAO-B have been fully described. MAO-A has 527 amino acids, and MAO-B has 520 amino acids. About 70% of the amino acid sequence of the two forms is homologous. The genes for both isoenzymes are located on the short arm of the human X chromosome. *MAO-A* and *MAO-B* are linked and have been located in the XP11.23-P11 and XP22.1 regions, respectively. The genes span about 70 kilobases (kb) and consist of about 15 exons and 14 introns. *MAO-A* has two messenger RNA (mRNA) transcripts of 2.1 and 5.0 kb in length. *MAO-B* has a 3-kb mRNA single transcript (Cesura and Pletscher 1992). A rare inherited disorder, Norrie's disease, is characterized by deletion of both genes; patients with this disorder have very severe mental retardation and blindness. Another rare inherited disorder is Brunner syndrome, caused by a mutation in *MAO-A*. It is characterized by impulsive aggressiveness and mild mental retardation (Brunner *et al.* 1993).

The subunit composition of MAO is unknown. The enzyme is primarily found in the outer mitochondrial membrane; flavin adenine dinucleotide is a cofactor for both MAO-A and MAO-B.

Because the cofactor domain is the same for both of the MAO isoenzymes, the structural differences responsible for substrate specificity are believed to lie in regions of the protein that bind to the hydrophobic moiety of the substrate. Although dopamine is considered to be a mixed substrate for both MAO-A and MAO-B, the breakdown of dopamine in the striatal regions of the brain is preferentially by MAO-B. In other regions, MAO-A may be more important. There may be regional differences as to which isoenzyme is responsible for the metabolism of other biogenic amines that are substrates for both forms of MAO (Cesura and Pletscher 1992). MAO-A levels are higher than MAO-B in infants, but this reverses with aging (Tong *et al.* 2013).

Enzyme Kinetics

The enzyme kinetics of MAO enzymes are complex and depend on the nature of the substrate. MAO-A and MAO-B have different intrinsic catalytic rates (Ramsay and Albreht 2018). Some substrates (e.g., tyramine) go through ping-pong mechanisms characterized by oxidation of the amine to the imine form, which is subsequently released from the reduced enzyme before reoxidation occurs. Other substrates (e.g., benzylamine) involve formation of a tertiary complex with the enzyme and oxygen (Husain *et al.* 1982; Pearce and Roth 1985; Ramsay and Singer 1991). The complex kinetics are influenced by oxygen levels and depend on the amine substrate (Ramsay and Albreht 2018).

Positron Emission Tomographic Studies of MAO-A in Psychiatric Disorders

[^{11}C]Harmine is a selective reversible PET radiotracer with high brain uptake that binds with high affinity to MAO-A. A study using this tracer reported highly significant elevations in brain MAO-A binding during episodes of major depressive disorder that persisted even after selective serotonin reuptake inhibitor (SSRI) treatment (Meyer *et al.* 2009). Interestingly, subjects with higher MAO-A levels had a higher rate of major depressive episode recurrence (Meyer *et al.* 2009).

Mechanism of Action

The target function of MAOIs is regulation of the monoamine content within the nervous system. Because MAO is bound to the outer surface of the plasma membrane of the mitochondria, in neurons MAO is unable to deaminate amines that are present inside stored vesicles and can metabolize only amines that are present in the cytoplasm. As a result, MAO maintains a low cytoplasmic concentration of amines within the cells. Inhibition of neuronal MAO produces an increase in the amine content in the cytoplasm.

Initially, it was believed that the therapeutic action of MAOIs was a result of this amine accumulation (Finberg and Youdim 1984; Murphy *et al.* 1984, 1987). More recently, it has been suggested that secondary adaptive mechanisms may be important for the antidepressant action of these agents.

After several weeks of treatment, MAOIs produce effects such as reductions in the numbers of b-adrenoreceptors, a_1- and a_2-adrenoreceptors, and serotonin type 1 (5-HT_1) and serotonin type 2 (5-HT_2) receptors. These changes are similar to those produced by long-term use of tricyclic antidepressants (TCAs) and other antidepressant treatments (Da Prada *et al.* 1984, 1989).

MAOIs can be subdivided on the basis of not only the particular type of enzyme they inhibit but also the type of inhibition they produce (reversible or irreversible). The reversible MAOIs are basically chemically inert substrate analogs. MAOIs are recognized as substrates by the enzyme and are converted into intermediates by the normal mechanism. These converted compounds react to the inactive site of the enzyme and form a stable bound enzyme. This effect occurs gradually, and there is usually a correlation between the plasma concentration of the reversible inhibitors and pharmacological action.

Pharmacological Profile

The classic MAOIs inhibit both forms of the enzyme and are divided into two main subtypes: hydrazine and nonhydrazine derivatives (Figure 10-1). The hydrazine derivatives, two of which are currently available (phenelzine and isocarboxazid), are related to iproniazid. One nonhydrazine derivative, tranylcypromine, is commercially available.

Among the selective MAOIs, clorgyline (which was never marketed in the United States) is an example of an irreversible inhibitor of MAO-A, whereas selegiline is an irreversible inhibitor of MAO-B. Moclobemide is the only reversible inhibitor of MAO-A on the market (available in the United Kingdom and Australia, but not in the United States).

Three classic MAOIs (i.e., phenelzine, isocarboxazid, and tranylcypromine) are of clinical interest. Clinicians must recognize that these drugs not only inhibit MAO but also exert other actions that may be clinically relevant. Thus, these compounds can block MAO uptake--tranylcypromine more than isocarboxazid or phenelzine. In addition, because tranylcypromine is structurally similar to amphetamine, it is believed to exert stimulant-like actions in the brain. Many issues are common to all three of these MAOIs.

Irreversible MAOIs

Indications and Efficacy

As discussed in the following subsections, irreversible MAOIs have been found to be effective in treating a variety of psychiatric disorders (Table 10-2).

Major Depressive Disorder and Depressive Disorder With Atypical Features

Many studies have examined the efficacy of the irreversible MAOIs in the treatment of different types of depression. MAOIs have been effective in the treatment of major depressive disorder and atypical depression (defined as depression with anxiety or chronic pain, reversed vegetative symptoms, and rejection sensitivity [Quitkin *et al.* 1990]) (Davidson *et al.* 1987a; Himmelhoch *et al.* 1982, 1991; Johnstone 1975; Johnstone and Marsh 1973; McGrath *et al.* 1986; Paykel *et al.* 1982; Quitkin *et al.* 1979, 1990, 1991; Rowan *et al.* 1981; Thase *et al.* 1992; Vallejo *et al.* 1987; White *et al.* 1984; Zisook *et al.* 1985). Although early studies of relatively low-dosage regimens suggested that the efficacy of MAOIs was lower than that of TCAs, more recent studies have documented that their efficacy is comparable.

Quitkin *et al.* (1979, 1991) reviewed both phenelzine and tranylcypromine studies in patients with either atypical depression or melancholic depression. The authors reported that phenelzine appeared to be effective for the treatment of atypical depression.

Relatively few studies have investigated MAOIs in patients with endogenous depression (i.e., depression without known precipitating factors). From the limited number of patient studies, it is difficult to conclude that phenelzine is effective in the treatment of these patients. In addition, very few well-controlled studies have compared tranylcypromine with placebo. Three of the four studies that compared tranylcypromine with placebo showed that tranylcypromine was more effective (Himmelhoch *et al.* 1982; Moises and Beckmann 1981; White *et al.* 1984). In one study, a nonsignificant trend was found that favored tranylcypromine (Nolen 1989). Studies have also documented tranylcypromine's efficacy in treating anergic depression and, at high dosages, treatment-resistant depression (Himmelhoch *et al.* 1982, 1991; Thase *et al.* 1992; White *et al.* 1984). In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, patients who had failed to respond to at least three treatment options were randomly assigned to receive tranylcypromine or a combination of extended-release venlafaxine and mirtazapine. Remission rates were modest for both the tranylcypromine group and the extended-release venlafaxine plus mirtazapine group, and the rates were not statistically different between groups (McGrath *et al.* 2006).

The heterogeneity of acetylation rates may account for some of the variance in response to phenelzine (Johnstone 1975; Johnstone and Marsh 1973; Paykel *et al.* 1982; Rowan *et al.* 1981). Approximately one-half of patients in a given population are slow acetylators. An initial study by Johnstone and Marsh (1973) suggested that slow acetylators improve more with phenelzine than do fast acetylators. Other researchers have been unable to confirm a relation between acetylation, acetylator type, and response to MAOIs.

Early studies suggested that irreversible MAOIs are particularly effective in patients with atypical depression. The concept of atypical depression remains controversial and has not been completely validated. The best differentiating criterion appears to be that phenelzine and other irreversible MAOIs are more effective than TCAs in treating patients with atypical depression (Cesura and Pletscher 1992; Quitkin *et al.* 1990; Zisook *et al.* 1985). A meta-review noted evidence that MAOIs are superior to TCAs, but not to SSRIs, in treating atypical depression (Cipriani *et al.* 2007).

Some studies have also suggested that MAOIs are effective in treating major depressive disorder and depression with melancholic features (Davidson *et al.* 1987a; McGrath *et al.* 1986; Vallejo *et al.* 1987). In a Cochrane Review, Lima and Moncrieff (2000) noted that MAOIs were comparable in efficacy to other classes of antidepressants in treating DSM-IV dysthymic disorder.

Panic Disorder

Both single-and double-blind studies have demonstrated the efficacy of phenelzine and iproniazid in treating panic disorder (Lydiard *et al.* 1989; Quitkin *et al.* 1990; Tyrer *et al.* 1973). About 50%-60% of patients with panic disorder respond to irreversible MAOIs. In the early stages of treatment, patients may have a worsening of symptoms. This is reduced in clinical practice by combining the MAOI with a benzodiazepine for the initial phase of treatment. It has been suggested that in addition to having an antipanic effect, phenelzine has an antiphobic action (Kelly *et al.* 1971). The time course of effect and the dosage used are similar to those for major depressive disorder.

Social Anxiety Disorder

Liebowitz *et al.* (1992) reported that phenelzine was effective in treating DSM-III (American Psychiatric Association 1980) social phobia. In an open-label study, Versiani *et al.* (1988) suggested that tranylcypromine was effective in treating this disorder as well. Versiani *et al.* (1992) also demonstrated the efficacy of the reversible MAOI moclobemide in a double-blind study. About 50% of patients responded to MAOIs, and the onset of response was gradual (usually about 2-3 weeks) (Liebowitz *et al.* 1992).

A Cochrane Review of pharmacotherapy for DSM-IV (American Psychiatric Association 1994) social phobia noted that whereas classic irreversible MAOIs were comparable in efficacy to SSRIs, reversible MAOIs were less efficacious (Stein *et al.* 2004).

Obsessive-Compulsive Disorder

Although initial case reports suggested that irreversible MAOIs may be effective in treating OCD (Jenike 1981), no double-blind studies conducted have indicated efficacy (Jenike *et al.* 1997).

Posttraumatic Stress Disorder

The classic MAOI phenelzine has been proven effective for the treatment of PTSD in single-blind trials (Davidson *et al.* 1987b) and in a double-blind crossover trial (Kosten *et al.* 1991).

Generalized Anxiety Disorder

MAOIs are not typically used to treat generalized anxiety disorder because the risk-benefit ratio favors the use of SSRIs, azapirones, or benzodiazepines. When they are used, MAOIs are selected primarily for treating treatment-resistant generalized anxiety disorder.

Bulimia Nervosa

Both phenelzine and isocarboxazid have been shown to be effective in treating some symptoms of bulimia nervosa (Kennedy *et al.* 1988; McElroy *et al.* 1989; Walsh *et al.* 1985, 1987).

Premenstrual Dysphoric Disorder

Preliminary studies and clinical experience have suggested that MAOIs may be effective in the treatment of premenstrual dysphoria (Glick *et al.* 1991).

Chronic Pain

MAOIs are believed to be effective in the treatment of atypical facial pain and other chronic pain syndromes. However, only limited data on these conditions are available.

Neurocognitive Disorders

The classic MAOIs have not been found to be effective for treating neurocognitive disorders such as Parkinson's disease and Alzheimer's disease. However, the MAO-B inhibitor selegiline has been shown to be effective in slowing the progression of Parkinson's disease (Cesura and Pletscher 1992), and two newer MAO-B inhibitors, rasagiline (TEVA Neuroscience 2014) and safinamide (U.S. WorldMeds 2017), are now approved for the treatment of Parkinson's disease (Dezsi and Vecsei 2017).

Side Effects and Toxicology

The side effects of irreversible MAOIs are generally not more severe or frequent than those of other antidepressants (Zisook 1984). The most frequent side effects are dizziness, headache, dry mouth, insomnia, constipation, blurred vision, nausea, peripheral edema, forgetfulness, fainting spells, trauma, urinary hesitancy, weakness, and myoclonic jerks. Loss of weight and appetite may occur with isocarboxazid use (Davidson and Turnbull 1982). Hepatotoxicity is rare with the currently available irreversible MAOIs, unlike with iproniazid. However, liver enzymes, such as aspartate transaminase and alanine transaminase, are elevated in 3%-5% of patients. Liver function tests must be done when patients have symptoms such as malaise, jaundice, and excessive fatigue.

Some side effects of irreversible MAOIs first emerge during maintenance treatment (Evans *et al.* 1982). These side effects include weight gain (which occurs in almost one-half of patients), edema, muscle cramps, carbohydrate craving, sexual dysfunction (usually anorgasmia), pyridoxine deficiency (Goodheart *et al.* 1991), hypoglycemia, hypomania, urinary retention, and disorientation. Peripheral neuropathy (Goodheart *et al.* 1991) and speech blockage (Goldstein and Goldberg 1986) are rare side effects of irreversible MAOIs. Weight gain is more of a problem with hydrazine compounds, such as phenelzine, than with tranylcypromine. Therefore, weight gain that is caused by hydrazine derivatives is an indication to switch to tranylcypromine. Edema is also more common with phenelzine than with tranylcypromine.

The management of some of these side effects can be difficult. Orthostatic hypotension is common with irreversible MAOIs. Addition of salt and salt-retaining steroids such as fludrocortisone (9-a-fluorohydrocortisone) is sometimes effective in treating orthostatic hypotension. Elastic support stockings are also helpful. Small amounts of coffee or tea taken during the day also keep the blood pressure elevated. The dose of fluorohydrocortisone should be adjusted carefully, because in elderly patients it could provoke cardiac failure resulting from fluid retention.

Sexual dysfunction that occurs with irreversible MAOIs is also difficult to treat. Common problems include anorgasmia, decreased libido, impotence, and delayed ejaculation (Harrison *et al.* 1985; Jacobson 1987). Cyproheptadine is sometimes effective in treating sexual dysfunction such as anorgasmia. Bethanechol may also be effective in some patients.

Insomnia occasionally occurs as an intermediate or late side effect of irreversible MAOIs. Changing the time of administration does not seem to help much, although dosage reduction may be helpful. Adding trazodone at bedtime is effective, but this should be done with caution. Myoclonic jerks, peripheral neuropathy, and paresthesias, when present, are also difficult to treat. When a patient has paresthesia, the clinician should evaluate for peripheral neuropathy and pyridoxine deficiency. In general, patients taking irreversible MAOIs should also receive concomitant pyridoxine therapy. When myoclonic jerks occur, patients can be treated with cyproheptadine.

Irreversible MAOIs also have the potential to suppress anginal pain; therefore, coronary artery disease could be overlooked or underestimated.

Patients with hyperthyroidism are more sensitive to irreversible MAOIs because of their overall sensitivity to pressor amines. Irreversible MAOIs can also worsen hypoglycemia in patients taking hypoglycemic agents such as insulin.

Dietary Interactions

After the introduction of irreversible MAOIs, several reports of severe headaches in patients who were taking these compounds were published ("Cheese and Tranylcypromine" 1970; Cronin 1965; Hedberg *et al.* 1966;

Simpson and Gratz 1992). These headaches were caused by a drug-food interaction. The risk of such an interaction is highest for tranylcypromine and lower for phenelzine, provided that the dosage of the latter remains low. However, the clinician must keep in mind that this interaction can occur even at low dosages with any of the classic MAOIs. The interaction of irreversible MAOIs with food has been attributed to increased tyramine levels. Tyramine, which has a pressor action, is present in a number of foods. It is normally broken down by the MAO enzymes and has both direct and indirect sympathomimetic actions. It has been suggested that the potentiation of tyramine by an MAOI may be secondary to increased release of norepinephrine rather than to the MAOI. Adrenaline would increase the indirect sympathetic activity of tyramine. The spontaneous occurrence of hypertensive crises in a few patients lends support to this hypothesis (O'Brien *et al.* 1992; Zajecka and Fawcett 1991).

The tyramine effect of food is potentiated by MAOIs 10-to 20-fold. A mild tyramine interaction occurs with about 6 mg of tyramine; 10 mg can produce a moderate episode, and 25 mg can produce a severe episode that is characterized by hypertension, occipital headache, palpitations, nausea, vomiting, apprehension, occasional chills, sweating, and restlessness. On examination, neck stiffness, pallor, mild pyrexia, dilated pupils, and motor agitation may be seen. The reaction usually develops within 20-60 minutes after ingestion of food. Occasionally, the reaction can be very severe and may lead to alteration of consciousness, hyperpyrexia, cerebral hemorrhage, and death. Death is exceedingly rare (Cooper 1989).

The classic treatment of the hypertensive reaction is phentolamine (5 mg) administered intravenously (Youdim *et al.* 1987; Zisook 1984). Nifedipine, a calcium channel blocker, has been shown to be effective (Stumpf 1988). Nifedipine has an onset of action of about 5 minutes, and it lasts approximately 3-5 hours; in fact, some clinicians have suggested that patients should carry nifedipine with them for immediate use in the event of a hypertensive crisis.

Because of the drug interaction of the classic MAOIs with food, clinicians usually make several dietary recommendations (Table 10-3). These recommendations are quite varied.

TABLE 10-3. **Food restrictions for monoamine oxidase inhibitors (MAOIs)**

To be avoided	To be used in moderation
Cheese (except cream cheese and cottage cheese)	Coffee
Overripe (aged) fruit (e.g., overripe bananas or avocados)	Chocolate
Fava beans	Colas
Sausage, salami	Tea
Beef and chicken livers	Soy sauce
Monosodium glutamate	Beer, other wines
Sauerkraut	
Pickled fish	
Brewer's yeast	
Fermented products	
Sherry, liqueurs	
Red wine	

MAOI diets recommend restriction of cheese (except cream cheese and cottage cheese), red wine, sherry, liqueurs, pickled fish, overripe (aged) fruit, brewer's yeast, fava beans, beef and chicken liver, and fermented products. Some diets recommend restriction of all alcoholic beverages, coffee, chocolate, colas, tea, yogurt, soy sauce, avocados, and bananas. Notably, many of the restricted foods--for example, avocados and bananas--rarely cause hypertensive crisis. For example, an interaction may occur only if overripe fruit is eaten or, in the case of bananas, if the skin is eaten (which is an uncommon practice in the United States). Similarly, unless a person ingests large amounts of caffeine, the interaction is usually not clinically significant. Although there is greater risk of noncompliance with highly restrictive diets, the clinician, when discussing restrictions and cautions with the patient, should emphasize the need to adhere to dietary restrictions and the potential risks that arise if they break the diet (Gardner *et al.* 1996).

Gillman's (2018) review of food science literature is a useful source to look for updated information on tyramine content of foods. High-tyramine foods can be encountered, but for the majority of people eating a regular diet, there are few foods that contain enough tyramine to provoke a major pressor response. But prudence is advised.

In evaluating patients who may have had a drug-food reaction, the clinician should evaluate the hypertensive reaction and differentiate it from histamine headache, which also can occur with an MAOI. Histamine headaches are usually accompanied by hypotension, colic, loose stools, salivation, and lacrimation (Cooper 1967). The clinician should provide both oral and printed instructions about food and drug interactions to patients who are taking classic MAOIs.

Norepinephrine reuptake inhibitors (e.g., reboxetine, desipramine, protriptyline, nortriptyline) are known to reduce the pressor response to tyramine (Dostert *et al.* 1997).

Drug-Drug Interactions

Drug-drug interactions are also extremely important concerns in patients taking irreversible MAOIs. The extensive inhibition of MAO enzymes by MAOIs increases the potential for a number of interactions with other drugs (Table 10-4). Of particular importance, many over-the-counter medications can interact with MAOIs. These medications include cough syrups containing sympathomimetic agents, which in the presence of an MAOI can precipitate a hypertensive crisis.

TABLE 10-4. Drug interactions with monoamine oxidase inhibitors (MAOIs)

Drug	Interaction	Comment
Other MAOIs (e.g., furazolidone, pargyline, procarbazine)	Potentiation of side effects; convulsions possible	Allow at least 1 week before changing to another MAOI
Tricyclic antidepressants (TCAs) (e.g., maprotiline, bupropion)	Possibility of severe side effects, such as hypertension and convulsions; serotonin syndrome	Allow at least 2 weeks before changing to an MAOI; combinations have been used occasionally for refractory depression
Carbamazepine	Low possibility of interaction; similar to TCAs	Same as for TCAs
Cyclobenzaprine	Low possibility of interaction; similar to TCAs	Same as for TCAs
Selective serotonin reuptake inhibitors (SSRIs)	Serotonin syndrome	Avoid combinations; allow at least 2 weeks before changing to an MAOI and 5 weeks if switching from fluoxetine to an MAOI
Stimulants (e.g., methylphenidate, dextroamphetamine)	Potential for increased blood pressure (hypertension)	Avoid combination
Buspirone	Potential for increased blood pressure (hypertension)	Avoid use; if used, monitor blood pressure
Meperidine	Possibility of severe, potentially fatal interaction (see	Avoid combination

Drug	**Interaction**	**Comment**

Dextromethorphan	Reports of brief psychosis; possible serotonin syndrome	Avoid high dosages
Direct sympathomimetics (e.g., L-dopa)	Increased blood pressure	Avoid use if possible; if they need to be used, use with caution
Indirect sympathomimetics (e.g., ephedrine)	Hypertensive crisis possible	Avoid use
Oral hypoglycemics (e.g., insulin)	Worsening of hypoglycemia possible	Monitor blood sugar levels and adjust medications
Fenfluramine	Serotonin syndrome possible	Avoid use
L-Tryptophan	Serotonin syndrome possible	Avoid use

More detailed lists are available (Gillman 1998). Another area of caution is the use of MAOIs in patients who need surgery. Potential interactions include those with narcotic drugs, especially meperidine. Meperidine administered with MAOIs can produce a syndrome characterized by coma, hyperpyrexia, and hypertension. This syndrome has been reported primarily with phenelzine; however, it has also been reported with tranylcypromine (Mendelson 1979; Stack *et al.* 1988). Stack *et al.* (1988) noted that this syndrome is most likely to occur with meperidine and that it may be related to that drug's serotonergic properties (similar to serotonin syndrome). Similar reactions have not been reported to any significant extent with other narcotic analgesics such as morphine and codeine. In fact, many patients probably receive these medications without problems. Only a small fraction of patients may have this interaction, and it could reflect a serotonin toxicity effect. In general, current opinion favors the use of morphine when intra-or postoperative narcotics are needed in patients taking MAOIs.

The issue of whether directly acting sympathomimetic amines interact with MAOIs is more controversial. Intravenous administration of sympathomimetic amines to patients receiving MAOIs does not provoke hypertension. When a bolus infusion of any of various catecholamines is given to healthy volunteer subjects who have been taking phenelzine or tranylcypromine for 1 week, a potentiation of the pressor effect of phenylephrine occurs, but no clinically significant potentiation of cardiovascular effects of norepinephrine, epinephrine, or isoproterenol occurs (Wells and Bjorksten 1989).

In general, direct sympathomimetic amine-MAOI interactions do not appear to produce significant cardiovascular problems. However, there is a low incidence of hypertensive episodes in the presence of indirect sympathomimetics. Ideally, these compounds should not be used in patients who are receiving MAOIs. A direct-acting compound is preferable to an indirect-acting compound.

Caution should be exercised when using MAOIs in patients with pheochromocytoma or with cardiovascular, cerebrovascular, or hepatic disease. Because phenelzine tablets contain gluten, they should not be given to patients with celiac disease.

Each patient should be given a card indicating that he or she is taking an MAOI and instructed to carry the card at all times. A medical bracelet indicating that the wearer takes an MAOI is also a good idea.

Specific Monoamine Oxidase Inhibitors

Phenelzine

Phenelzine, a hydrazine derivative, is a potent irreversible MAOI and is the best studied of the MAOIs.

Pharmacokinetics

Phenelzine is a substrate as well as an inhibitor of MAO. Major identified metabolites of phenelzine include phenylacetic acid and *p*-hydroxyphenylacetic acid. Phenelzine undergoes acetylation, and therefore drug levels are lower in fast acetylators than in slow acetylators. However, because phenelzine is an irreversible inhibitor, plasma concentrations are not relevant. The antidepressant effect, the degree of inhibition of MAO, and the amount of free phenelzine excreted in the urine are all significantly greater in slow acetylators than in fast acetylators (Baker *et al.* 1999).

Indications

Phenelzine is useful in the treatment of major depressive disorder, atypical depression, panic disorder, social phobia, and atypical facial pain (see section "Indications and Efficacy" earlier in this chapter).

Side Effects

The primary side effects of phenelzine are similar to those of other MAOIs. Hepatitis secondary to phenelzine may occur in rare cases (< 1 in 30,000). The most difficult side effect, often leading to discontinuation, is postural hypotension.

Contraindications

The contraindications to phenelzine include known sensitivity to the drug, pheochromocytoma, congestive heart failure, and history of liver disease. (In addition, see sections "Dietary Interactions" and "Drug-Drug Interactions" earlier in this chapter.)

Isocarboxazid

Isocarboxazid is an irreversible MAOI of the hydrazine type.

Pharmacokinetics

Isocarboxazid is rapidly absorbed from the gastrointestinal tract and is metabolized in the liver. It is primarily excreted as hippuric acid. Its half-life is of little interest because it is an irreversible MAOI. Chemically, isocarboxazid is 5-methyl-3-isoxazolecarboxylic acid 2-benzylhydrazide. Isocarboxazid is a colorless crystalline substance with very little taste.

Indications

Isocarboxazid is the least studied of the MAOIs. It is indicated for the treatment of depression.

Side Effects

The side effects of isocarboxazid are similar to those of phenelzine, described earlier in this section. Postural hypotension is the most common problem.

Contraindications

The contraindications to isocarboxazid are similar to those of phenelzine, described earlier in this section.

Tranylcypromine

Tranylcypromine, a nonhydrazine irreversible MAOI, increases the concentration of norepinephrine, epinephrine, and 5-HT in the CNS. Tranylcypromine has a mild stimulant effect.

Pharmacokinetics

Limited data exist on the pharmacokinetics of tranylcypromine. The drug is excreted within 24 hours. The dynamic effect lasts for up to 5 days after withdrawal. There is considerable debate about whether tranylcypromine is metabolized to amphetamine; most studies in the literature indicate that this does not occur.

Indications

Tranylcypromine is indicated for the treatment of major depressive disorder without melancholia.

Side Effects

The side effects of tranylcypromine are similar to those of other MAOIs. In addition, problems with physical dependence on tranylcypromine have been reported. Thus, withdrawal symptoms, such as anxiety, restlessness, depression, and headache, may occur. Syndrome of inappropriate antidiuretic hormone (SIADH) has been reported with tranylcypromine. Rare cases of toxic hepatitis have also been reported. Tranylcypromine can lead to increased agitation, insomnia, and restlessness compared with phenelzine.

Contraindications

The contraindications to tranylcypromine are the same as those for phenelzine, described earlier in this section. In addition, in view of the greater potential for hypertensive episodes, tranylcypromine should be used with particular caution in patients with cerebrovascular or cardiovascular disease.

Moclobemide

Moclobemide, a reversible inhibitor of MAO-A enzyme (Amrein *et al.* 1989), has a higher potency in vivo than in vitro. Therefore, it has been suggested that moclobemide is a prodrug and that it is metabolized to a form with higher affinity for MAO-A than the parent compound. After single-or repeated-dose administration of moclobemide, the recovery of MAO-A activity is much quicker than that seen with other MAOIs. One of the metabolites of moclobemide does inhibit MAO-B; however, this action is minimally significant in humans. When administered to rats, moclobemide increases the concentration of 5-HT, norepinephrine, epinephrine, and dopamine in rat brain (Haefely *et al.* 1992). These effects are short-lasting, and they parallel the time course of MAO-A inhibition. In addition, unlike with irreversible inhibitors, repeated administration does not increase the inhibition.

Moclobemide only partially potentiates the blood pressor effect of oral tyramine (Da Prada *et al.* 1989). This is because it is a reversible inhibitor with a low affinity for the MAO isoenzymes and is easily displaced by the pressor amines ingested in food. On the basis of these studies, moclobemide is thought to be safer than irreversible MAOIs.

Pharmacokinetics

After oral administration of moclobemide, peak plasma concentrations are reached within 1 hour. The drug is about 50% bound to plasma proteins and is extensively metabolized; only 1% of the compound is excreted (unchanged) in the urine. The half-life of the compound is approximately 12 hours. Moclobemide is extensively metabolized; 95% of the administered dosage is excreted in the urine. The metabolites are pharmacologically inactive. The presence of food reduces the rate (but not the extent) of moclobemide absorption.

Indications

Moclobemide has been studied in all types of depressive disorders (Gabelic and Kuhn 1990; Larsen *et al.* 1991; Rossel and Moll 1990). Controlled trials have found that it is superior to placebo. In addition, moclobemide has been found to be as effective as

imipramine, desipramine, clomipramine, and amitriptyline in the treatment of depression. The dosage required is 300-600 mg/day.

Unlike the classic MAOIs, moclobemide has been found to be effective in treating both endogenous and nonendogenous depression. In addition, in combination with antipsychotics, the drug seems to be effective in treating psychotic depression (Amrein *et al.* 1989). Moclobemide has also been effective in treating bipolar endogenous depression.

Versiani *et al.* (1992) compared phenelzine, moclobemide, and placebo and reported that both phenelzine and moclobemide were superior to placebo in treating patients with social phobia. Given the efficacy of classic MAOIs in the treatment of other psychiatric disorders, such as bulimia, panic disorder, and PTSD, it is likely that patients with such disorders would also respond to a reversible MAOI. Additional trials of moclobemide are required to confirm its utility in other psychiatric disorders.

Side Effects

Nausea was the only side effect noted to be greater in patients taking moclobemide than in patients taking placebo. Thus, the profile of moclobemide seems to be ideal in that it causes few or no major side effects. Case reports have shown no toxicity after overdoses of up to 20 g (Amrein *et al.* 1989).

Dietary Interactions

Intravenous tyramine pressor tests indicate that a single dose of moclobemide increases tyramine sensitivity (Cusson *et al.* 1991). However, this increase is small compared with the increase associated with other MAOIs. Under most conditions, there appears to be limited drug-food interaction. However, to minimize even mild tyramine pressor effects, the recommended action is to administer moclobemide after a meal rather than before it. In a study in which tyramine was administered in doses up to 100 mg, inpatients pretreated with moclobemide had no significant changes in blood pressure. The drug also has minimal effect on cognitive performance and no effect on body weight or hematological parameters (Wesnes *et al.* 1989; Youdim *et al.* 1987).

Drug-Drug Interactions

Several studies have examined potential drug-drug interactions with moclobemide (Amrein *et al.* 1992). No drug interaction with lithium has been reported. No interactions with benzodiazepines or antipsychotics have been reported (Amrein *et al.* 1992). Parallel data suggest that moclobemide can potentiate the effects of meperidine; therefore, a narcotic-MAOI interaction may occur. Combination with other antidepressants (including SSRIs) is best avoided in view of potential serotonin toxicity. Until proven otherwise, it would be prudent to avoid the combination of moclobemide with opiates like meperidine and other drugs that can increase serotonin. A pharmacokinetic interaction has been observed with cimetidine that requires the reduction of the moclobemide dose because cimetidine reduces the clearance of moclobemide.

Selegiline Hydrochloride

Selegiline hydrochloride is an irreversible MAO-B inhibitor (Cesura and Pletscher 1992). Its primary use is in the treatment of Parkinson's disease, as an adjunct to L-dopa

and carbidopa. The average dosage for Parkinson's disease is 5-10 mg/day. The exact mechanism of action of MAO-B in Parkinson's disease is unknown (Gerlach *et al.* 1996; Hagan *et al.* 1997; Lyytinen *et al.* 1997). In the United States, selegiline dosage forms include tablets, capsules, orally disintegrating tablets, and extended-release transdermal patches (see next section, "Selegiline Transdermal System").

Pharmacokinetics

Selegiline is metabolized to levoamphetamine, methamphetamine, and *N*-desmethylselegiline. Selegiline hydrochloride undergoes significant first-pass metabolism following oral administration. Transdermal delivery avoids the first-pass effect and provides greater levels of unchanged drug and reduced levels of metabolites compared with the oral regimen. The time to reach the peak plasma concentration is less than 1 hour. The elimination half-life of selegiline is about 1.5 hours. There is at least a threefold increase in the area under the curve (AUC) of selegiline with food (Mahmood 1997).

Indications and Efficacy

The efficacy of oral selegiline in treating depression has not been well studied. Quitkin *et al.* (1984) showed that selegiline was superior to placebo administered to patients with depression in a 6-week double-blind study. Dosages of more than 10-20 mg/day were needed. The dosage required for treating depression may be much higher than that required to treat Parkinson's disease. At higher dosages, dietary interactions could occur. Early studies also found that selegiline is of modest benefit in patients with Alzheimer's disease (Lawlor *et al.* 1997).

Side Effects

The few side effects that have been noted with selegiline include nausea, dizziness, and light-headedness. When the drug is abruptly discontinued, nausea, hallucinations, and confusion have been reported.

Dietary Interactions

Because MAO-B is not involved in the intestinal tyramine interaction, dietary interaction with selegiline (at low dosages of 5-10 mg/day) would probably be minimal. An interaction between selegiline and narcotics has been reported and should be kept in mind.

Drug-Drug Interactions

Selegiline's potential drug interactions are similar to those of other MAOIs, and there is a risk for serotonin syndrome if selegiline is combined with other drugs (including SSRIs) that can increase serotonin.

Selegiline Transdermal System

The selegiline transdermal system (STS) was developed to overcome limitations of orally administered MAOIs, particularly dietary tyramine restrictions. STS does not overcome drug-drug interactions. It bypasses the gut, thereby reducing drug-food interactions. The pharmacokinetic and pharmacodynamic properties promote the inhibition of MAO-A and MAO-B in the CNS while avoiding significant inhibition of intestinal and liver MAO-A enzymes. Three different strengths of the STS patch are currently marketed: 20 mg/20 cm^2, 30 mg/30 cm^2, and 40 mg/40 cm^2. The three patch sizes deliver 24-hour doses of selegiline averaging 6 mg, 9 mg, and 12 mg, respectively. Use of the 6-mg patch does not call for dietary modification. A restricted "MAOI diet" is advised for the higher-dosage 9-mg and 12-mg patches to avoid any risk of hypertensive crisis. Patients are strongly advised to follow these restrictions.

Pharmacokinetics

Following dermal application of the STS patch, 25%-30% of the selegiline content on average is delivered systemically over 24 hours. Consequently, the degree of drug absorption is one-third higher than the average amounts of 6-12 mg/24 hours. In comparison with oral dosing, transdermal dosing results in substantially higher exposure to selegiline and lower exposure to metabolites.

Indications and Efficacy

The efficacy of STS as a treatment for major depressive disorder was established in two placebo-controlled studies of 6 and 8 weeks' duration in adult outpatients with major depressive disorder. In both studies, patients were randomly assigned to receive double-blind treatment with drug patch or placebo. The 6-week trial showed that 6 mg/24 hours was significantly more effective than placebo, as assessed by scores on the 17-item Hamilton Rating Scale for Depression (Ham-D) (Amsterdam 2003). In an 8-week dosage titration trial, depressed patients receiving the drug patch (starting dosage was 6 mg/24 hours, with possible increases to 9 mg/24 hours or 12 mg/24 hours based on clinical response) showed significant improvement compared with those receiving placebo on the primary outcome measure, the 28-item Ham-D total score (Feiger *et al.* 2006). In another trial, 322 patients with symptoms meeting DSM-IV-TR (American Psychiatric Association 2000) criteria for major depressive disorder who had responded during an initial 10-week open-label treatment phase were randomly assigned either to continuation at the same dosage or to placebo under double-blind conditions for observation of relapse. In this double-blind phase, patients receiving continued STS experienced a significantly longer time to relapse (Amsterdam and Bodkin 2006). The efficacy of STS was also studied in a double-blind study of adolescents with depression. There was no significant difference between patients receiving STS and those receiving placebo (DelBello *et al.* 2014).

Side Effects

The main side effects with STS are diarrhea, application site reactions (e.g., skin irritation, rash), and insomnia.

Drug-Drug Interactions

Potential drug-drug interactions for STS are the same as for other MAOIs.

Conclusion

Various MAOIs have been shown to be effective in treating a wide variety of psychiatric disorders, including depression, panic disorder, social phobia, and PTSD. The classic

MAOIs are currently used only rarely as first-line medication because of potential dietary interactions and other long-term side effects. The reversible inhibitors of MAO-A enzyme, such as moclobemide, which have fewer side effects and no dietary restrictions compared with classic MAOIs, are unlikely to be introduced in the United States. In fact, the risk-benefit ratio for these compounds is highly favorable compared with other antidepressants. The MAO-B inhibitor selegiline is used to reduce the progression of Parkinson's disease. Its utility in treating other degenerative disorders is currently being assessed. STS reduces dietary interactions when used at low dosages and is now approved for the treatment of major depressive disorder. New applications and a wider use of these compounds may be found in the near future.

Tricyclic and Tetracyclic Drugs

J. Craig Nelson, M.D.

The tricyclic antidepressants hold an important place in the history of treatments for depression. They were the first class of antidepressant compounds to be widely used for depression and remained the first-line treatment for more than 30 years. Observations of their activity led to theories of drug action involving norepinephrine and serotonin. Indeed, this "psychopharmacological bridge" suggested that alterations of these neurotransmitters might cause depression (Bunney and Davis 1965; Prange 1964; Schildkraut 1965). As a result of extensive research on the tricyclics, the field developed several key principles to guide the management of depressive illness. For example, clinicians recognized the importance of not only providing an adequate medication dosage and duration during acute treatment but also sustaining symptom improvements during continuation. Adverse events associated with the tricyclics required that psychiatrists become familiar with a variety of syndromes such as anticholinergic delirium, delayed cardiac conduction, and orthostatic hypotension. The observation that tricyclic plasma concentrations varied widely stimulated interest in the relationship of these drug concentrations to hepatic metabolism and clinical activity. The field was introduced to the concepts of genetic polymorphisms in the cytochrome P450 (CYP) enzyme system. Finally, knowledge of how these drugs work became the basis for the discovery of new drugs such as the selective serotonin reuptake inhibitors (SSRIs).

History and Discovery

In 1957, the Swiss psychiatrist Roland Kuhn investigated the clinical effects of imipramine, in part to determine whether its sedative properties might be useful for humans (Kuhn 1958, 1970). He found that although imipramine was not useful in

calming agitated patients, it ameliorated symptoms in patients with depression. After imipramine was introduced, several other antidepressant compounds were developed and marketed.

Structure-Activity Relations

Tricyclic and tetracyclic compounds are categorized based on their chemical structure (Figure 11-1). The tricyclics have a central three-ring structure--hence the name. The tertiary-amine tricyclics, such as amitriptyline and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated to secondary amines such as desipramine and nortriptyline. The tetracyclic compound maprotiline has a four-ring central structure. Five tertiary amines have been marketed in the United

States: amitriptyline, clomipramine, doxepin, imipramine, and trimipramine. The three secondary-amine compounds are desipramine, nortriptyline, and protriptyline. All of these compounds, in addition to amoxapine and maprotiline, have been approved for use in major depressive disorder with the exception of clomipramine, which is approved for use only in OCD in the United States.

FIGURE 11-1. Chemical structures of the tricyclic and tetracyclic antidepressants.

The structure of the side chain is important for the function of tricyclic antidepressants. The tertiary tricyclic agents--amitriptyline, imipramine, and clomipramine--are more potent in blocking the serotonin transporter. The secondary tricyclics are much more potent in blocking the norepinephrine transporter (Table 11-1) (Bolden-Watson and Richelson 1993; Tatsumi *et al.* 1997).

The structure of amoxapine differs from the structures of the other tricyclics. With a central three-ring structure and a side chain unlike those of the tricyclics, amoxapine is structurally closer to the antipsychotic loxapine, from which it is derived. Like the secondary tricyclics, amoxapine is a potent norepinephrine reuptake inhibitor. Unlike the other compounds in this group, amoxapine--particularly its metabolite 7-hydroxyamoxapine--blocks postsynaptic dopamine receptors (Coupet *et al.* 1979). As a result, it is the only compound in the group that has antipsychotic activity in addition to antidepressant effects.

Maprotiline also differs from the others in this group. Although maprotiline is tetracyclic, its side chain is identical to that in desipramine, nortriptyline, and protriptyline. As would be predicted from this similarity, maprotiline is most potent in blocking the norepinephrine transporter (Randrup and Braestrup 1977).

Pharmacological Profile

Reuptake Blockade

Early in the history of the tricyclic and tetracyclic antidepressants, the ability of these compounds to block the transporter site for norepinephrine was described (Axelrod *et al.* 1961) (see Table 11-1). The tertiary amines have greater affinity for the serotonin transporter, whereas the secondary amines are relatively more potent at the norepinephrine transporter. During administration of amitriptyline, imipramine, or clomipramine, these tertiary amines are demethylated to secondary amines; thus, both serotonergic and noradrenergic effects occur. In addition, because dopamine is inactivated by norepinephrine transporters in the frontal cortex (Bymaster *et al.* 2002), norepinephrine reuptake inhibitors would be expected to increase dopamine concentrations in that region.

The initial reuptake blockade is followed by a specific sequence of events (Blier *et al.* 1987; Charney *et al.* 1991; Tremblay and Blier 2006). After reuptake blockade, levels of serotonin and norepinephrine increase. As a result of inhibitory feedback from the presynaptic autoreceptors, the firing rate of the presynaptic neuron slows and concentrations of the major metabolites of serotonin and norepinephrine decrease rapidly. In the serotonin system, the presynaptic autoreceptor is desensitized over a 10-to 14-day period, and the tonic firing rate returns to its pretreatment rate. With both a normal firing rate and reuptake blockade, serotonin transmission is enhanced. In contrast, the firing rate of noradrenergic neurons remains inhibited with chronic treatment (Szabo and Blier 2001), suggesting that somatodendritic a_2-autoreceptors do not desensitize. Norepinephrine concentrations increase at postsynaptic sites such as the hippocampus and frontal cortex, which may indicate desensitization of terminal a_2-autoreceptors. With chronic treatment, the postsynaptic b-adrenergic receptor is downregulated or decreased in density (Sulser *et al.* 1978). Current evidence suggests that b-adrenergic receptor downregulation is likely a compensatory change. Overall, chronic administration of norepinephrine reuptake inhibitors results in enhanced noradrenergic transmission. This effect manifests as enhanced formation of second-messenger cyclic adenosine monophosphate (Duman *et al.* 1997) and is reflected clinically by a persistent increase in heart rate (Roose *et al.* 1998; Rosenstein and Nelson 1991).

The tricyclic agents also sensitize or upregulate postsynaptic serotonin_{1A} (5-HT_{1A}) receptors (de Montigny and Aghajanian 1978). These changes further enhance the effects of serotonin. In addition, tricyclics downregulate serotonin_2 (5-HT_2) receptors (Peroutka and Snyder 1980). In preclinical experiments, the effects of serotonin were enhanced when an antagonist blocked the 5-HT_2 receptor (Lakoski and Aghajanian 1985; Marek *et al.* 2003). Some tricyclics, particularly amoxapine and doxepin (and to some extent amitriptyline), have 5-HT_2 antagonist properties that are relatively comparable to their reuptake potency (see Table 11-1) (Tatsumi *et al.* 1997).

Secondary Effects

The tricyclic and tetracyclic compounds have a variety of additional actions mediated by other receptors (Cusack *et al.* 1994; Richelson and Nelson 1984) (see Table 11-1). For example, these compounds block muscarinic receptors, producing anticholinergic effects. Although these anticholinergic effects have generally been thought to mediate the adverse effects of the tricyclics and tetracyclics, a double-blind randomized crossover study of 19 individuals with major depressive disorder reported that the anticholinergic drug scopolamine had a beneficial effect on depressive and anxious symptoms (Furey and Drevets 2006). Consistent with this finding, the cholinesterase inhibitor donepezil increased the risk of depression relapse among older adults when given as an adjunct to an SSRI (Reynolds *et al.* 2011). Tricyclics also block histamine_1 (H_1) receptors and a_1- and a_2-adrenergic receptors, resulting in a variety of other effects (as discussed later in "Side Effects and Toxicology"). Tricyclics act on voltage-gated sodium channels, which explains their adverse cardiac effects; however, these same actions may contribute to the beneficial effects of these antidepressants on pain (Liang *et al.* 2014; Priest and

Kaczorowski 2007). The potency of secondary effects of tricyclics and tetracyclics varies considerably. Among the tricyclics, amitriptyline is the most anticholinergic and desipramine is the least. Doxepin is the most potent H_1 antagonist among the tricyclics, but mirtazapine is even more potent. The consequences of these secondary effects are discussed later in this chapter ("Side Effects and Toxicology").

Pharmacokinetics and Disposition

Absorption

Absorption of the tricyclic and tetracyclic drugs occurs in the small intestine and is rapid and reasonably complete. Peak levels are reached within 2-8 hours after ingestion, with the exception of protriptyline (6-12 hours) and maprotiline (8 hours or longer). Although peak levels may have implications for side effects, they are relatively unimportant with respect to efficacy because the antidepressant action of these drugs occurs over several weeks.

Volume of Distribution

The tricyclic and tetracyclic compounds are basic lipophilic amines and are concentrated in a variety of tissues throughout the body. As a result, they have a high volume of distribution. For example, concentrations of these drugs in cardiac tissue exceed concentrations in plasma.

Plasma Protein Binding

Tricyclic and tetracyclic antidepressants are extensively bound to plasma proteins (e.g., 90% or greater) because of their lipid solubility. Exceptions are the hydroxy metabolites, which have lower plasma protein binding than the parent compounds.

First-Pass Metabolism

After absorption, the tricyclics are taken up in the circulation but pass first through the liver, where metabolism of the drug begins. As a result, the amount of compound that enters the systemic circulation is reduced.

Hepatic Metabolism

Hepatic metabolism is the principal method of clearance for the tricyclic and tetracyclic compounds. Only a small portion of drug is eliminated by the kidneys. Rates of hepatic metabolism vary widely from person to person, resulting in dramatic differences in steady-state plasma concentrations. For example, in a sample of 83 white inpatients given a fixed dose of desipramine (2.5 mg/kg), steady-state plasma concentrations ranging from 20 to 934 ng/mL were observed (Nelson 1984). Elimination half-lives for most of the tricyclic and tetracyclic compounds average about 24 hours or longer; thus, these drugs can be given once per day (Table 11-2). Amoxapine has a shorter half-life than the other tricyclics and is an exception.

Hepatic metabolism of the tricyclics and tetracyclics occurs along two principal pathways. In one pathway, *demethylation of the side chain* converts the tertiary amines to secondary amines and involves several CYP isoenzymes, including CYP1A2, CYP3A4, and CYP2C19. In the other pathway, *hydroxylation of the ring structure* is regulated by the CYP2D6 isoenzyme and produces hydroxy metabolites (Brosen *et al.* 1991). In some cases, the levels of the metabolite are substantial. The concentration of 10-hydroxynortriptyline usually exceeds that of the parent compound (Bertilsson *et al.* 1979). Usually 2-hydroxydesipramine is present at levels approximately 40%-50% of those of the parent compound, but these ratios are quite variable and depend on the hydroxylation rate (Bock *et al.* 1983; Potter *et al.* 1979). Hydroxynortriptyline and hydroxydesipramine both block the norepinephrine transporter (Bertilsson *et al.* 1979; Potter *et al.* 1979) and have antidepressant activity (Nelson *et al.* 1988b; Nordin *et al.* 1987). Hydroxyimipramine and hydroxyamitriptyline are present at very low concentrations and are clinically unimportant. The hydroxy metabolites are then conjugated and excreted. The conjugated metabolites are not active.

The principal metabolic pathway for amoxapine is hydroxylation, during which 7-hydroxyamoxapine and 8-hydroxyamoxapine are produced (Coupet *et al.* 1979). These compounds differ: whereas 7-hydroxyamoxapine has high-potency antipsychotic properties but a short half-life, 8-hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

The hepatic isoenzymes are under the control of specific genes, and gene loci for several of these isoenzymes, including CYP2D6, have been identified. Approximately 5%-10% of white individuals are homozygous for the recessive autosomal CYP2D6 trait, resulting in deficient hydroxylation of desipramine and nortriptyline (Brosen *et al.* 1985; Evans *et al.* 1980). Approximately 50% of individuals of Asian descent carry the *CYP2D6*10* allele, which is associated with intermediate metabolism of CYP2D6 substrates (Ji *et al.* 2002). For example, the elimination half-life of nortriptyline is doubled in individuals homozygous for this allele (Yue *et al.* 1998).

P-Glycoprotein and the Blood-Brain Barrier

P-glycoprotein (P-gp) is located at the blood-brain barrier and acts as an efflux pump. P-gp protects the organism from exogenous compounds. It is hypothesized that by limiting uptake of antidepressants into the CNS, P-gp contributes to medication resistance. Most tricyclics are substrates of P-gp (Akamine *et al.* 2012; O'Brien *et al.* 2012). The effectiveness of P-gp is reduced in the presence of P-gp inhibitors (e.g., verapamil and quinidine), and these agents would be expected to increase CNS concentrations of P-gp substrates (Weiss *et al.* 2003). However, the utility of adjunctive treatment with a P-gp inhibitor to improve outcomes has not been demonstrated.

P-gp is encoded by the gene *ABCB1*. Polymorphisms of *ABCB1* decrease the efficiency of P-gp and should result in higher CNS concentrations of P-gp substrates. Although an early study showed that remission with P-gp substrates was associated with *ABCB1* polymorphisms (Uhr *et al.* 2008), a review and meta-analysis of the association of *ABCB1* variants with outcomes reported considerable variability in the findings of 16 studies (Breitenstein *et al.* 2015). Furthermore, the investigators in the two largest studies included in the meta-analysis found that none of the *ABCB1* variants were associated with response to P-gp substrate antidepressants. These findings suggest limited applicability of genotype *ABCB1* as a predictor of response in depression.

Linear Kinetics

Most of the tricyclics have linear kinetics--that is, their concentration increases in proportion to dose within the therapeutic range. There are exceptions. Desipramine, for example, has nonlinear kinetics at the usual dosage range (Nelson and Jatlow 1987). In cases of overdose, pharmacokinetics are more likely to change from linear to nonlinear metabolism, and the clinician cannot assume that usual rates of drug elimination will be maintained.

Effects of Aging

Changes in the pharmacodynamics and pharmacokinetics of medications occur with aging, but they vary in importance (Greenblatt *et al.* 1998). The ratio of fat to lean body mass increases, and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness, but their clinical importance is usually relatively minor because of the dramatic variability of hepatic metabolism. The activity of the CYP3A4 pathway slows with age (von Moltke *et al.* 1995), and concentrations of the tertiary amines are increased somewhat in older individuals (Abernethy *et al.* 1985). However, most studies of nortriptyline (Katz *et al.* 1989; Young *et al.* 1984) and desipramine (Abernethy *et al.* 1985; Nelson *et al.* 1985, 1995) indicate that the ratios of blood level to dosage are relatively unaffected by aging, suggesting that the CYP2D6 isoenzyme is not similarly affected. Renal clearance of the hydroxy metabolites does decrease with age (Nelson *et al.* 1988a; Young *et al.* 1984). As a result, concentrations of hydroxynortriptyline may be substantially elevated in older patients.

In children, the clearance of tricyclic compounds is increased. Half-lives of imipramine are shorter and ratios of desmethylimipramine to imipramine are higher, consistent with more rapid metabolism (Geller 1991; Rapoport and Potter 1981). However, a study of desipramine in children reported that the clearance of both desipramine and hydroxydesipramine was increased, so ratios of the hydroxy metabolite to the parent compound were not elevated (Wilens *et al.* 1992).

Relationship of Plasma Concentration to Clinical Action

Plasma Concentration and Response

Marked interindividual variability of tricyclic plasma concentrations was described by Hammer and Sjoqvist (1967). This finding suggested that drug-level monitoring might ensure that therapeutic blood levels are achieved and might help avoid toxic levels. In carefully selected inpatients with endogenous or melancholic major depressive disorder, treatment with adequate levels of imipramine or desipramine resulted in robust response rates of approximately 85% (Glassman *et al.* 1977; Nelson *et al.* 1982). However, similar relationships have proven difficult to demonstrate in outpatients with depression. In outpatients, drug-placebo differences are often small, and the effect of drug treatment is harder to detect. Outpatients with depression may be more heterogeneous and may include individuals who are not responsive to any drug treatment. It is logical to conclude that blood-level relationships determined for inpatients with severe depression might be used as a guide to treat outpatients, but this assumption has not been empirically validated.

The American Psychiatric Association Task Force on the Use of Laboratory Tests in Psychiatry (1985) reviewed studies relating tricyclic plasma levels and response. Its members concluded that a relationship had been demonstrated for imipramine, desipramine, and nortriptyline (see Table 11-2). Data on the relationship between blood level and response in depression are limited or conflicting for the other tricyclic and tetracyclic compounds.

Plasma Concentration and Toxicity

Blood-level monitoring may help avoid toxicity. Delirium, cardiac conduction delay, and seizure are associated with elevated tricyclic plasma concentrations (Livingston *et al.* 1983; Preskorn and Irwin 1982; Preskorn and Simpson 1982). Following overdose, tricyclic blood levels greater than 1,000 ng/mL can be achieved, and the risks of delirium, stupor, cardiac abnormalities, and seizures are all substantially increased (Nelson and Spyker 2017; Preskorn and Irwin 1982; Rudorfer and Young 1980; Spiker *et al.* 1975). The value of blood-level monitoring to avoid serious adverse effects has been difficult to demonstrate because rates of serious toxicity are low; large samples are required to demonstrate any increase in risk at higher blood levels.

If blood-level monitoring is undertaken, the clinician should bear in mind that many factors--including laboratory variability, blood sampling errors, missed doses, and biological variability--can affect drug concentrations. For this reason, the clinician should not view the concentration reported as a precise measure. Because concentrations vary across such a wide range, it may be very helpful to know whether the level is low, moderate, or high.

Dosage-Adjustment Techniques

The demonstrated relationship between timed drug concentrations after a single tricyclic dose and the steady-state level achieved indicates that plasma levels could be used to rapidly adjust dose; however, laboratory constraints make this impractical. A more clinically feasible method is to start the drug at a low or moderate fixed dosage, obtain a patient blood sample after 5-7 days of administration, and then make further adjustments based on that level. There are exceptions. Elderly patients with depression often require gradual dosing to assess tolerance. For patients with panic attacks, lower starting dosages are used to avoid exacerbation. Doxepin and nortriptyline are available as oral solutions for patients who may not be able to tolerate tablets or capsules or for adjusting very low dosages.

Mechanism of Action

In early studies, investigators observed that the tricyclic agents blocked uptake of monoamines at the norepinephrine and serotonin transporters (Axelrod *et al.* 1961). This drug effect was quickly put forward as a possible mechanism of action. The observation that reserpine, which depletes presynaptic catecholamines, might induce depression in vulnerable individuals was consistent with this hypothesis (Goodwin and Bunney 1971). Confirmation that norepinephrine and serotonin do, in fact, mediate the action of monoamine reuptake inhibitors was provided by subsequent challenge studies in patients with depression. For example, administration of a tryptophan-free diet rapidly depleted serotonin and caused relapse among patients with depression who were successfully treated with a serotonin reuptake inhibitor but not a norepinephrine reuptake inhibitor (Delgado *et al.* 1990). In addition, administration of a-methyl-*p*-tyrosine, which interrupts the synthesis of catecholamines, caused relapse among patients who were successfully treated with noradrenergic agents but not among those receiving serotonergic drugs (Delgado *et al.* 1993). These studies provide supporting evidence that serotonin and norepinephrine mediate antidepressant effects, but they do not necessarily imply that alterations in these neurotransmitter systems are central to the etiology of depression.

Subsequent research on the mechanism of action of the tricyclics and other antidepressant drugs has shifted to also consider factors affecting postsynaptic signal transduction (Manji *et al.* 1995). Such factors include the coupling of G proteins to the adrenergic receptor or to adenylyl cyclase and the activity of membrane phospholipases and protein kinases. Other newer targets, including glucocorticoid receptors (Barden 1996), neurotrophic factors (Duman *et al.* 1997), and gene expression (Lesch and Manji 1992; Nibuya *et al.* 1996; Schwaninger *et al.* 1995), have been explored.

Indications and Efficacy

Major Depressive Disorder

The efficacy of tricyclic and tetracyclic compounds in major depressive disorder is well established (Agency for Health Care Policy and Research 1993; Davis and Glassman 1989). Imipramine is the most extensively studied tricyclic antidepressant, in part because new drugs are often compared with it. In 30 of 44 placebo-controlled studies, imipramine was more effective than placebo. If data from these studies are combined, 65% of 1,334 patients *completing* treatment with imipramine were substantially improved, whereas 30% of those taking placebo improved. *Intention-to-treat* response rates for placebo-controlled studies of imipramine in outpatients were 51% for imipramine and 30% for placebo (Agency for Health Care Policy and Research 1993). The other tricyclic and tetracyclic antidepressants appeared comparable to imipramine in efficacy.

The tricyclic compounds are also effective when used for maintenance treatment. Frank *et al.* (1990) found that imipramine, at the full dosage, effectively maintained improvement for nearly 80% of patients with depression for a 3-year period, whereas only 10% of the placebo group achieved this outcome. In this study, maintenance psychotherapy had an intermediate effect, with approximately 30% of patients remaining well. In practice, clinicians may encounter patients with chronic depression, residual symptoms, or comorbid medical and psychiatric disorders. For such patients, the effects of acute and maintenance treatment are less robust.

The FDA has approved all of the tricyclic and tetracyclic compounds discussed in this chapter for the treatment of depression, with the exception of clomipramine, which is approved for OCD only. In Europe, clomipramine is also used for depression; in fact, it has been regarded by many as the most potent antidepressant.

Major Depressive Disorder With Melancholic Features (Severe Depression)

The efficacy of tricyclic compounds seems to vary in different subtypes of depression. Early studies of tricyclic compounds were frequently conducted with hospitalized patients with depressive disorder with melancholic features (severe depression). Tricyclic antidepressants were effective for these patients. In fact, the tricyclics may be especially effective in this group. Two studies of imipramine and desipramine reported response rates of approximately 85% for hospitalized patients with severe depression who did not have a history of treatment-resistant depression, did not have prominent personality disorder, received an adequate dosage and attained an adequate plasma concentration of the drug, and completed treatment (Glassman *et al.* 1977; Nelson *et al.* 1982).

When the SSRIs were introduced, it was suggested that they might be less effective than the tricyclic antidepressants in treating severe or melancholic depression. However, in a large meta-analysis of more than 100 comparison studies, Anderson (2000) found that tricyclic antidepressants and SSRIs had comparable efficacy. In a separate meta-analysis of 25 inpatient studies (Anderson 1998), the advantage of the tricyclics appeared limited to those with dual action--namely, amitriptyline and clomipramine. In outpatient populations, the designation of melancholia does not appear to predict an advantage for tricyclic antidepressants versus SSRIs (Anderson and Tomenson 1994; Montgomery 1989).

Major Depressive Disorder With Anxious Distress

The use of tricyclics to treat anxious depression--or *depressive disorder with anxious distress* in DSM-5 (American Psychiatric Association 2013)--has been studied frequently. Doxepin, amoxapine, and maprotiline are FDA approved for use in patients with depression and symptoms of anxiety. Direct comparison studies, however, have shown little indication that one tricyclic is better than another for treatment of depression

with anxious distress. Compared with depressed patients who are not prominently anxious, depressed patients who are anxious may respond less well to amitriptyline (Kupfer and Spiker 1981), imipramine (Roose *et al.* 1986), and desipramine (Nelson *et al.* 1994). Yet these drugs are still more effective than placebo for individuals with depression and anxiety, and it is not established that another drug class is more effective for these patients.

Depressive Disorder With Atypical Features

A series of studies examined the efficacy of imipramine for patients with depressive disorder with atypical features (Liebowitz *et al.* 1984, 1988). Imipramine was more effective than placebo but significantly less effective than the monoamine oxidase inhibitor (MAOI) phenelzine. Other investigators have reported the value of switching from a tricyclic to an MAOI for patients with tricyclic-refractory depression with atypical features (McGrath *et al.* 1987; Thase *et al.* 1992). In fact, the utility of the diagnosis of atypical depression was supported in large part by the differential response to these drug classes.

Major Depressive Disorder With Psychotic Features

Glassman *et al.* (1975) observed that imipramine was less effective for patients with major depressive disorder who had delusions. Subsequently, Chan *et al.* (1987) reviewed several studies involving more than 1,000 patients and found that antidepressants--usually tricyclics--given alone were effective for approximately two-thirds of patients with depression without psychotic features but only for about one-third of individuals with depressive disorder with psychotic features. Several open-label studies reviewed elsewhere (Nelson 1987) and one prospective study (Spiker *et al.* 1985) reported that the tricyclics, when combined with an antipsychotic, are effective in treating psychotic depression.

Anton and Burch (1990) suggested that because of its antipsychotic effects, amoxapine might be effective for depressive disorder with psychotic features. In a double-blind study, they demonstrated that amoxapine was comparable in efficacy to the combination of perphenazine and amitriptyline in treating psychotic depression (Anton and Burch 1990).

Major Depressive Episodes in Bipolar Disorder

Fifty years ago, MAOI antidepressants were suggested to be more effective than the tricyclics in treating depressive episodes in bipolar disorder (Himmelhoch *et al.* 1972). Later, Himmelhoch *et al.* (1991) demonstrated in a double-blind study that tranylcypromine was more effective than imipramine for bipolar depression. Because tricyclics are more likely than other agents to induce mania (Wehr and Goodwin 1987), they are not recommended for monotherapy of bipolar disorders.

Persistent Depressive Disorder

The new DSM-5 diagnostic category *persistent depressive disorder* includes both chronic major depressive disorder and the previous DSM-IV (American Psychiatric Association 1994) diagnosis dysthymic disorder. Imipramine appears to be effective in treating chronic depression and to be relatively comparable to sertraline in efficacy (Keller *et al.* 1998; Kocsis *et al.* 1988). Imipramine and desipramine have both been studied in controlled trials in chronic depression. Imipramine was more effective than placebo for the acute treatment of DSM-III-TR (American Psychiatric Association 1987)-defined dysthymia (Thase *et al.* 1996), and desipramine was more effective than placebo for maintenance treatment (Miller *et al.* 2001).

Major Depressive Disorder in Older Adults

Gerson *et al.* (1988) reviewed studies of tricyclic antidepressants in older patients reported prior to 1986. They found 13 placebo-controlled trials but noted several methodological problems. Although tricyclics were effective, the overall response rates for older patients appeared to be lower than those for nonelderly patients (Agency for Health Care Policy and Research 1993). Katz *et al.* (1990) conducted one of the first placebo-controlled trials examining nortriptyline in the treatment of patients older than 80 years living in a residential care facility. Nortriptyline was more effective than placebo. The dosages used and levels achieved were similar to those in younger individuals. This investigation by Katz *et al.* (1990) remains the only one to date showing an advantage for an antidepressant over placebo in nursing home patients with depression.

Depressive Disorders in Children

In children and adolescents with depression, the tricyclic antidepressants have not demonstrated superiority over placebo (Ryan 1992).

Panic Disorder

Although none of the tricyclic or tetracyclic drugs are approved for use in panic disorder, imipramine was the first drug described for such use (Klein 1964). The efficacy of both tertiary and secondary tricyclics has been demonstrated in controlled trials (Jobson *et al.* 1978; Munjack *et al.* 1988; Zitrin *et al.* 1980). In treating panic disorder, the drug is initiated at a low dose to avoid exacerbation of panic symptoms.

Obsessive-Compulsive Disorder

Unlike depression, which responds to a variety of antidepressant agents, OCD appears to require treatment with a serotonergic agent. Clomipramine, the most serotonergic of the tricyclics, is FDA approved for use in OCD, and its efficacy in this disorder is well established (Greist *et al.* 1995). Studies comparing the effectiveness of clomipramine with that of noradrenergic agents such as desipramine reported that clomipramine was substantially superior (Leonard *et al.* 1989). Although the SSRIs are effective in treating OCD, clomipramine has been suggested to be superior (Greist *et al.* 1995). Whether this suggested superiority is attributable to the dual mechanism of clomipramine or to other factors is unclear.

Attention-Deficit/Hyperactivity Disorder

The efficacy of the stimulant drugs in treating ADHD is well established. The tricyclics, especially desipramine, also appear to be of value. In one study, desipramine (at dosages greater than 4 mg/kg) given for 3-4 weeks was effective for two-thirds of children, whereas placebo was effective for only 10% (Biederman *et al.* 1989). Desipramine

was also found to be more effective than placebo for adults with ADHD (Wilens *et al.* 1996). One advantage of desipramine is its low potential for abuse. Unfortunately, five cases of sudden death in children (all younger than age 12 years) treated with desipramine were reported in the early 1990s (Riddle *et al.* 1991, 1993). As a result, desipramine is contraindicated for children younger than age 12 years (discussed in greater detail in "Side Effects and Toxicology"). Given that tricyclics as a group share similar adverse cardiac effects, there is reason to be concerned that other tricyclics might also have safety issues in young children (see also Chapter 60, "Treatment of Child and Adolescent Disorders").

Pain Syndromes

The tricyclics and the tetracyclic maprotiline have been widely used in various chronic pain syndromes. In a review of the literature, O'Malley *et al.* (1999) identified 56 controlled studies involving tricyclic antidepressant therapy for various pain syndromes, including headache (21 studies), fibromyalgia (18 studies), functional gastrointestinal syndromes (11 studies), idiopathic pain (8 studies), and tinnitus (2 studies). Salerno *et al.* (2002) identified seven more placebo-controlled trials of tricyclics or maprotiline used for chronic back pain. These agents were quite effective; the mean effect size (0.87) and the number needed to treat (approximately three) in the pain trials were more robust than those usually observed in placebo-controlled studies of depression. Therefore, the analgesic activity of these compounds was not simply the result of their antidepressant effects.

The mechanism of these agents' analgesic effects appears to differ from that of their antidepressant effects. The antinociceptive actions of antidepressants result from actions on descending norepinephrine and serotonin pathways in the spinal cord (Yoshimura and Furue 2006). In animals, the antinociceptive effects of norepinephrine reuptake inhibitors and combined norepinephrine-serotonin reuptake inhibitors seem to be more potent than those of SSRIs (Mochizucki 2004). In humans, there is some evidence that the combined-action agents amitriptyline and clomipramine are more effective than selective agents (Eberhard *et al.* 1988; Max *et al.* 1992; Panerai *et al.* 1990). In humans, antidepressant dosing and timing of effects for pain differ from those for depression. For example, the usual dosages of amitriptyline required for pain management (approximately 75 mg/day) are lower than those required to treat depression (150-300 mg/day) and response occurs more quickly, usually within the first 1 or 2 weeks.

Other Indications

Imipramine is FDA approved for the treatment of nocturnal enuresis in children, and controlled trials indicate efficacy (Rapoport *et al.* 1980). The dose of imipramine is usually 25-50 mg taken at bedtime. Amitriptyline and nortriptyline also appear to be useful for this indication, although they are not FDA approved for use in this disorder. Their mechanism of action is unclear but may in part be anticholinergic. Given the serious cardiac risks associated with desipramine use for children younger than 12 years (see the earlier subsection "Attention-Deficit/Hyperactivity Disorder"), use of tricyclics other than desipramine might also pose safety risks for this population. However, the low imipramine doses used to treat pediatric nocturnal enuresis may reduce this risk.

Tricyclic antidepressants have been extensively studied in patients with schizophrenia. However, in the absence of a major depressive episode, these agents appear to be of limited value (Siris *et al.* 1978).

The more sedating tricyclics have been used to treat insomnia. Oral doxepin (Silenor) at low dosages acts primarily as a histaminic antagonist and is FDA approved for insomnia. Because of its antihistaminic effects, topical doxepin (Zonalon 5% topical cream) has also been used for pruritus and is FDA indicated for short-term management of moderate pruritus in atopic dermatitis and lichen simplex chronicus.

Side Effects and Toxicology

Distinguishing side effects during tricyclic treatment from the somatic symptoms of depression can be complicated. During treatment, patients may attribute somatic symptoms to drug side effects even if the symptoms were preexisting (Nelson *et al.* 1984).

Another general factor contributing to side effects is patient vulnerability. For example, the presence of orthostatic hypotension prior to treatment is associated with orthostatic hypotension during treatment (Glassman *et al.* 1979). Seizures are most likely for a patient with a history of them (Rosenstein *et al.* 1993). Cardiac conduction problems are most likely for patients with a preexisting conduction delay (Roose *et al.* 1987a).

Antidepressant drugs affect a variety of organs and can produce adverse effects. The in vitro potency or affinity of antidepressant compounds for various receptor sites (see Table 11-1) is one factor determining the likelihood that specific side effects will be produced. A related issue is how the potency of a secondary effect relates to that of the primary action of the drug. If the secondary effect is more potent, it will occur at concentrations below the therapeutic level of the drug. For example, orthostatic hypotension often occurs at low plasma concentrations, and the antihistaminic effects of doxepin occur at doses well below antidepressant doses. Conversely, the proarrhythmic and proconvulsant effects of the tricyclic antidepressants become more pronounced at elevated blood levels or those encountered in overdose.

Central Nervous System Effects

The principal action of the tricyclic and tetracyclic agents in the CNS is to reduce the symptoms of depression. Nondepressed subjects given imipramine may feel sleepy, quieter, light-headed, clumsy, and tired. These effects are generally unpleasant (Dimascio *et al.* 1964).

The anticholinergic and antihistaminic effects of tricyclic and tetracyclic antidepressants can produce confusion or delirium. The incidence of delirium is dose dependent, with the risk for delirium increasing at blood levels greater than 300 ng/mL (Livingston *et al.* 1983; Preskorn and Simpson 1982). Delirium risk appears to be higher with the more anticholinergic agents such as amitriptyline. Patients with concurrent dementia are particularly vulnerable to the development of delirium, and the more anticholinergic tricyclics should be avoided these individuals. Intramuscular or intravenous physostigmine can be used to reverse or reduce delirium symptoms, but physostigmine has a short duration of action that makes its continued use difficult.

Seizures can occur with all of the tricyclic and tetracyclic agents and are related to dosage and blood level (Rosenstein *et al.* 1993). For clomipramine, seizure risk is reported to be 0.5% at dosages up to 250 mg/day, but at dosages of 300 mg/day or greater, seizure risk increases to 2.1% (McTavish and Benfield 1990). The seizure risk for imipramine and amitriptyline was not well established at the time of marketing. Two postmarketing studies reported that seizure risks varied from 0 to 0.6% or 0.7% for various tricyclic compounds and were clearly dose related (Jick *et al.* 1983; Peck *et al.* 1983). Seizure risk is substantially increased following overdose (Spiker *et al.* 1975). Cumulative data to date suggest that amoxapine, clomipramine, and maprotiline present the highest seizure risk among these agents (Johannessen Landmark *et al.* 2016). Seizure risk is increased for patients with predisposing factors such as a history of seizures, the presence of a brain injury, or the use of antipsychotics. The mechanism by which tricyclics produce seizures is not well understood.

A fine, rapid tremor can occur with the use of tricyclic agents. Because tremors are dose dependent, they tend to occur at higher blood levels. Development of a tremor may indicate an elevated blood level (Nelson *et al.* 1984).

Because the 7-hydroxy metabolite of amoxapine has antipsychotic properties, administration of amoxapine carries the potential risk for neuroleptic malignant syndrome and tardive dyskinesia. Although these adverse events are rare, the seriousness of the risk and the availability of alternatives suggest that amoxapine should be reserved for indications that warrant medication with antipsychotic properties.

Anticholinergic Effects

The tricyclics block muscarinic receptors and can cause a variety of anticholinergic side effects such as dry mouth, constipation, blurred vision, and urinary hesitancy. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (see Table 11-1). Amitriptyline is the most potent, and desipramine is the least anticholinergic. Amoxapine and maprotiline also have minimal anticholinergic effects.

Although anticholinergic effects are bothersome, they are usually not serious. These effects can, however, become severe. An ocular crisis in patients with narrow-angle glaucoma can occur, and this acute condition is associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Paralytic ileus has been described but is rare.) In these conditions, the medication must be discontinued and appropriate supportive measures instituted. Elderly patients are at greatest risk for severe adverse events. The incidence of severe anticholinergic adverse reactions is increased by concomitant administration of other anticholinergic agents. Use of a tricyclic with weak anticholinergic properties, such as nortriptyline or desipramine, can help reduce the likelihood of these adverse effects.

Anticholinergic side effects may benefit from other interventions. Bethanechol (Urecholine; 25 mg tid or qid) may be helpful for patients with urinary hesitancy. The regular use of stool softeners helps manage constipation. Patients with narrow-angle glaucoma who are receiving pilocarpine eye drops regularly can be treated with a tricyclic, as can those who have had an iridectomy. Tricyclic agents do not affect patients with chronic open-angle glaucoma.

Antihistaminic Effects

Several of the tricyclic compounds and maprotiline have clinically significant antihistaminic effects. Doxepin, the most potent H_1 receptor antagonist among the tricyclics, is more potent than diphenhydramine but less potent than mirtazapine. Central H_1 receptor blockade can contribute to sedation and delirium and appears to be related to increased appetite and associated weight gain. Because of their sedating effects, the tricyclic antidepressants, especially amitriptyline, have been used as hypnotics. Given their cardiac effects and lethality in overdose, this practice should be discouraged.

Cardiovascular Effects

Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment (Glassman *et al.* 1979). This effect can occur with all of the tricyclics but appears to be less pronounced with nortriptyline (Roose *et al.* 1981; Thayssen *et al.* 1981). The a_1-adrenergic blockade associated with the tricyclics contributes to orthostatic hypotension; however, the postural reflex is primarily affected. Resting supine blood pressure may be unaffected or can even be elevated (Walsh *et al.* 1992). Orthostatic hypotension is most likely to occur or is most severe among patients with preexisting orthostatic hypotension (Glassman *et al.* 1979). This condition is also aggravated by concurrent antihypertensive medications, especially volume-depleting diuretic agents. Elderly individuals are more likely to have preexisting hypotension and are also more vulnerable to the consequences of orthostatic hypotension, such as falls and hip fractures.

Orthostatic hypotension often occurs at low medication blood levels. Gradual dosage adjustment may allow accommodation to the subjective experience of light-headedness, but the actual orthostatic blood pressure changes do not accommodate within a reasonable period (e.g., 4 weeks) (Roose *et al.* 1998). Consequently, tricyclic antidepressants may not be suitable for patients who experience serious symptomatic orthostatic hypotension. Fludrocortisone (Florinef) has been used to raise blood pressure, but in this author's experience is not very effective. If patients are receiving antihypertensives, it may be possible and helpful to reduce the dosage of these agents.

Desipramine has been reported to raise *supine* blood pressure in young women (ages 18-45 years), although it is not clear that this effect is limited to that age group (Walsh *et al.* 1992). The elevation in blood pressure may be similar to that reported for venlafaxine.

Tachycardia occurs with all of the tricyclics, not just the more anticholinergic agents. Both supine and postural pulse changes can occur, and the standing pulse can be markedly elevated. In a study of nortriptyline dosed to a therapeutic plasma concentration, investigators found a mean pulse increase of 11% (8 beats per minute) (Roose *et al.* 1998). Patients do not accommodate to the pulse rise, which can persist for months (Rosenstein and Nelson 1991). Tachycardia is more prominent in young patients, who appear to be more sensitive to sympathomimetic effects, and is one of the most common reasons for drug discontinuation among adolescents. A persistent pulse rise, however, increases cardiac work and may be clinically significant for patients with ischemic heart disease.

The effect of tricyclic antidepressants on cardiac conduction has been a subject of great interest. Cardiac arrhythmia is the principal cause of death after tricyclic overdose (Spiker *et al.* 1975). Apparently, through inhibition of sodium/potassium adenosine triphosphatase, the tricyclics stabilize electrically excitable membranes and delay conduction, particularly His ventricular conduction. Consequently, the tricyclics have type I antiarrhythmic qualities or quinidine-like effects.

At therapeutic blood levels, tricyclic antidepressants can have beneficial effects on ventricular excitability. However, tricyclics can cause heart block in patients with preexisting conduction delay (Glassman and Bigger 1981; Roose *et al.* 1987b). A pretreatment QTc interval of 450 milliseconds or greater indicates that conduction is already delayed and the patient is not a candidate for tricyclic treatment. High drug plasma levels (e.g., imipramine plasma concentrations > 350 ng/mL) increase the risk of first-degree atrioventricular heart block (Preskorn and Irwin 1982). The tricyclic antidepressants do not reduce cardiac contractility or cardiac output (Roose *et al.* 1987a).

Glassman *et al.* (1993), noting that the type I antiarrhythmic drugs routinely given after myocardial infarction actually increase the risk of sudden death, suggested that the tricyclics may pose similar risks. The risk of sudden death is also increased when heart rate variability is reduced, and the tricyclics reduce heart rate variability (Roose *et al.* 1998).

As mentioned earlier in the subsection "Attention-Deficit/Hyperactivity Disorder," five cases of sudden death were reported in children younger than age 12 years who were receiving desipramine (Riddle *et al.* 1991, 1993). It was suggested that the immature conduction system in some children might render them more vulnerable to the cardiac effects of desipramine. However, no cardiac abnormalities were observed in a study of 71 children with 24-hour cardiac monitoring (Biederman *et al.* 1993). These findings suggest that cardiac events in children are not dose dependent and that electrocardiogram monitoring is not likely to identify those at risk.

Hepatic Effects

Acute hepatitis has been associated with the use of imipramine (Horst *et al.* 1980; Moskovitz *et al.* 1982; Weaver *et al.* 1977) or desipramine (Powell *et al.* 1968; Price *et al.* 1983). Mild increases in liver enzymes (less than three times the normal level) are not uncommon and usually can be monitored safely over a period of days or weeks. Enzyme changes do not appear to be related to drug concentrations (Price *et al.* 1984). Acute hepatitis is relatively uncommon but can occur. The etiology is not well established, but the condition seems to represent a hypersensitivity reaction in some cases. Tricyclic-induced acute hepatitis is characterized by very high enzyme levels (e.g., aspartate aminotransferase levels greater than 800 U/L), which develop within days. The enzyme pattern can be either hepatocellular or cholestatic. Enzyme changes may precede clinical symptoms, especially in the hepatocellular form. If a random blood test indicates mildly elevated liver enzymes, then enzyme levels can be followed for a few days. Because liver enzyme levels increase rapidly in acute hepatitis, the condition will become evident quickly and will be easily distinguished from persistent mild elevations in enzyme levels.

Acute hepatitis is dangerous and potentially fatal. If a patient develops this condition, the antidepressant must be discontinued and should not be introduced again because the next reaction may be more severe.

Other Side Effects

Increased sweating can occur with the tricyclic compounds; occasionally, sweating can be marked. Carbohydrate craving also can occur and can lead to significant weight gain when coupled with antihistaminic effects. Weight gain appears to be greater with the tertiary compounds than with the secondary agents. Sexual dysfunction has been described with the tricyclics but appears to be less common than with the SSRIs. This side effect appears to be associated with the more serotonergic compounds, such as clomipramine. Tricyclic antidepressants can cause allergic skin rashes, which are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported; fortunately, these are very rare.

Overdose

Because antidepressants are used by patients with depression who are at risk for overdose, the lethality of antidepressant drugs in overdose is of great concern. A tricyclic medication overdose of 10 times the total daily dosage can be fatal (Gram 1990; Rudorfer and Robins 1982). Death most commonly results from cardiac arrhythmia. However, seizures, CNS depression, and respiratory depression also can occur. Although the use of tricyclics in the treatment of depression has declined, amitriptyline remains widely used for other indications, such as pain. The total number of amitriptyline-associated deaths reported to U.S. poison control centers from 2000 to 2014 was greater than the total number of deaths associated with all other tricyclic and tetracyclic agents combined or the total number of deaths associated with all second-generation antidepressants (Nelson and Spyker 2017). All of the tricyclic and tetracyclic compounds can be dangerous in overdose. However, two reports indicated that the ratio of deaths to the number of prescriptions written was relatively low for clomipramine compared with the other tricyclic antidepressants (Cassidy and Henry 1987; Farmer and Pinder 1989). Among medications with at least 1,000 single drug exposures in the U.S. poison control database, clomipramine had significantly lower morbidity and mortality risks than the other tricyclic antidepressants (Nelson and Spyker 2017).

Teratogenicity

The long history of tricyclic use without observation of birth defects provides support for the safety of these agents. Of course, patients must be informed of the possible risks and benefits of taking these medications and the risks of discontinuation before they agree to treatment. The risk for recurrence is particularly high during or following pregnancy for patients with a prior history of depression.

If tricyclics are continued during pregnancy, dosage adjustment may be required because of metabolic changes (Altshuler and Hendrick 1996). The infant may experience drug withdrawal after delivery, which is characterized by tachypnea, cyanosis, irritability, and poor sucking reflex. Drugs in this class should be discontinued 1 week before delivery if possible. The tricyclics are excreted in breast milk at concentrations similar to those in plasma but the actual quantity delivered is very small, so drug levels in the infant are usually undetectable (Rudorfer and Potter 1997; also see Chapter 63, "Psychopharmacology During Pregnancy and Lactation").

Drug-Drug Interactions

Both pharmacodynamic and pharmacokinetic drug interactions should be considered.

Pharmacodynamic Interactions

Serious pharmacodynamic interactions can occur between the tricyclics and MAOIs. The most dangerous scenario--administration of a large dose of a tricyclic to a patient who is already taking an MAOI--could result in a sudden increase in catecholamines and a potentially fatal hypertensive reaction. Tricyclics and MAOIs have been used together to treat patients with refractory depression (Goldberg and Thornton 1978; Schuckit *et al.* 1971). When used in combination, treatment is begun at lower dosages and either the two compounds are started together or the tricyclic is started first.

The most common pharmacodynamic interaction involving the tricyclics occurs when they are added to other sedating agents, resulting in increased sedation. By blocking the norepinephrine transporters, the tricyclics block the uptake and thus interfere with the actions of guanethidine and tyramine. Desipramine and the other tricyclics reduce the effect of clonidine.

Quinidine is an example of a drug with a potential for dynamic and kinetic interaction with tricyclics. Because the tricyclics have quinidine-like effects, the effects of tricyclics and quinidine on cardiac conduction are potentially additive. In addition, quinidine is a potent CYP2D6 isoenzyme inhibitor that can increase tricyclic levels, further adding to the problem.

Pharmacokinetic Interactions

Several drugs can block the metabolic pathways of the tricyclics, resulting in higher and potentially toxic blood levels of drug. Desipramine has been of particular interest because it is metabolized via the CYP2D6 isoenzyme and there are no major alternative pathways. Inhibition of CYP2D6 can result in very high desipramine plasma levels, and toxicity can occur (Preskorn *et al.* 1990). As described in the previous section ("Pharmacodynamic Interactions"), quinidine is a very potent CYP2D6 inhibitor. Fluoxetine and paroxetine, duloxetine, bupropion, and some antipsychotics also inhibit CYP2D6. Fluoxetine and paroxetine at usual dosages increase desipramine levels, on average, three-to fourfold in individuals who are extensive metabolizers (Preskorn *et al.* 1994). CYP2D6 inhibitors would be expected to block nortriptyline metabolism, but the magnitude of this interaction has not been well studied.

Because the tertiary tricyclics are metabolized by several pathways (CYP1A2, CYP3A4, and CYP2C19), a selective inhibitor of one pathway would be unlikely to have a significant effect on their plasma levels. Although numerous drug interactions have been described, many are of doubtful clinical significance (for comprehensive reviews, see Nemeroff *et al.* 1996 and Pollock 1997).

Enzyme induction can also occur, which may render the tricyclic acted upon ineffective. Unlike enzyme inhibition, which occurs quickly, enzyme induction requires the synthesis of new enzymes and the full effect may take 2-3 weeks to develop. Barbiturates and carbamazepine are potent inducers of CYP3A4, which can become an important alternative pathway for some tricyclics.

Nicotine induces the CYP1A2 pathway and may lower concentrations of the tertiary tricyclics, but the secondary tricyclics (e.g., desipramine, nortriptyline) are less affected.

Acute ingestion of alcohol can reduce first-pass metabolism, resulting in higher tricyclic levels. This interaction is important because tricyclic overdose is often associated with alcohol ingestion. Conversely, chronic use of alcohol appears to induce hepatic isoenzymes and may lower tricyclic levels (Shoaf and Linnoila 1991).

The tricyclics themselves appear to be weak enzyme inhibitors, and few clinically significant interactions have been described. The tertiary tricyclics compete with warfarin for some metabolic enzymes (e.g., CYP1A2) and may increase warfarin levels.

Conclusion

The tricyclic drugs were the mainstay of treatment for depression for three decades. Although the second-generation antidepressants appear to be better tolerated, no new agent has been shown to be more effective than the tricyclics, and, if anything, there has been concern that the new agents may be less effective. The tricyclics were "dirty" drugs; that is, they had multiple actions. Although their side effects have been emphasized, these multiple actions may contribute to their efficacy. Not only does amitriptyline block uptake of serotonin, but its metabolite blocks uptake of norepinephrine, and amitriptyline is also a 5-HT_2 antagonist. Furthermore, the anticholinergic effects of amitriptyline may contribute to its antidepressant activity. The principal drawback of this class of agents is the risk for serious cardiac adverse effects. Tricyclics can aggravate arrhythmia in patients with a preexisting conduction delay. These agents also may increase the risk of sudden death in children and in patients with ischemic heart disease. Moreover, a week's supply of medication taken in overdose can be fatal. Because of these adverse effects, it is unlikely that there will be a resurgence of interest in tricyclic antidepressants. Nevertheless, the efficacy of these agents across a range of disorders, including pain, illustrates the potential advantages of antidepressant drugs with multiple actions.

CHAPTER 12

Fluoxetine and Fluvoxamine

Fluoxetine

The introduction of fluoxetine as the first selective serotonin reuptake inhibitor (SSRI) approved in the United States was a cultural phenomenon and an important advance in psychopharmacology. Considerable evidence has demonstrated that fluoxetine has a broad spectrum of clinical usefulness. There is a consensus, however, that the commercial success of fluoxetine (and subsequently marketed SSRIs) derives from its advantageous safety profile.

History and Discovery

Serotonin is an indoleamine with wide distribution in plants, animals, and humans. Pioneering histochemistry by Falck *et al.* (1962) demonstrated that serotonin was localized within specific neuronal pathways and cell bodies. These originate principally from two discrete nuclei: the medial and dorsal raphe. Although regional variations exist, several limbic structures manifest especially high levels of serotonin (Amin *et al.* 1954).

However, serotonin levels in the CNS represent only a small fraction of those in the body (Bradley 1989). Because serotonin does not cross the blood-brain barrier, it must be synthesized locally. Serotonin is released into the synapse from the cytoplasmic and vesicular reservoirs (Elks *et al.* 1979). Following its release, serotonin is principally inactivated by reuptake into nerve terminals through a sodium/potassium adenosine triphosphatase-dependent carrier (Shaskan and Snyder 1970). The transmitter is subsequently subjected to either degradation by monoamine oxidase (MAO) or vesicular storage. Abnormalities in central serotonin function have been hypothesized to underlie disturbances in mood, anxiety, satiety, cognition, aggression, and sexual drive, to highlight a few.

Structure-Activity Relations

Significant structural and activity differences exist among the SSRIs (Thomas *et al.* 1987). Their chemical structures help illustrate this diversity (Figure 12-1). In contrast to paroxetine and sertraline, which exist as single isomers, fluoxetine (like citalopram) is a racemate. Fluoxetine is less potent than paroxetine in vitro and less selective for serotonin reuptake inhibition than citalopram. However, in vitro potency does not necessarily equate with in vivo dosing experience, clinical efficacy, or adverse event profile.

FIGURE 12-1. Chemical structures of selective serotonin reuptake inhibitors and selected tricyclic antidepressants.

Although the tricyclic antidepressants (TCAs), like the SSRIs, antagonize serotonin receptors (Dempsey *et al.* 2005; Eisensamer *et al.* 2003), they also exhibit differing inhibitory activity at other receptor targets and consequently differ in their adverse event profiles (Hall and Ogren

1981; Snyder and Yamamura 1977; U'Prichard *et al.* 1978). These other targets include histaminergic, a$_1$-adrenergic, and muscarinic receptors. For fluoxetine, the median inhibitory concentration at histaminergic and adrenergic sites is in the micromolar range and thus unlikely to be of clinical significance. Activity at the muscarinic receptor is negligible for fluoxetine. Stauderman *et al.* (1992) reported that fluoxetine and paroxetine inhibited the binding of ^{3}H-labeled nitrendipine to L-type calcium channels; however, this was at concentrations that probably exceeded those reached during in vivo treatment of depression.

In summary, in vitro radioligand-binding techniques have shown that fluoxetine has a lower probability of many of the troublesome side effects associated with TCAs and is relatively selective in its serotonin reuptake inhibition.

Pharmacological Profile

Serotonin

The action of any SSRI extends beyond the inhibition of serotonin reuptake. At least 14 different serotonin receptor subtypes reside at pre-and postsynaptic locations (Fuller 1996). Serotonin$_{1A}$ (5-HT$_{1A}$) binding sites include both somatodendritic and presynaptic autoreceptors (which inhibit serotonin firing) and postsynaptic receptors. The latter are predominantly hippocampal, and their sensitivity is increased after chronic antidepressant exposure (Aghajanian *et al.* 1988; Castro *et al.* 2003).

After long-term administration, many antidepressants downregulate or reduce the density of serotonin$_2$ (5-HT$_2$) binding sites in the rat frontal cortex (Peroutka and Snyder 1980). Some, but not all, SSRIs have been associated with this effect (Fraser *et al.* 1988). Fluoxetine normalizes 5-HT$_{1A}$ density in rats (Sodero *et al.* 2006). SSRIs, as a drug class, normalize both 5-HT$_{1A}$ and 5-HT$_2$ receptor density in patients with depression (Leonard 1992).

The mechanisms by which fluoxetine and other SSRIs interact with the human serotonin transporter (SERT) are not fully understood. Some evidence suggests that the effect of fluoxetine on SERT is partially based on the presence of SERT promoter polymorphism, so it can either increase or decrease SERT expression, depending on an individual's genotype (Little *et al.* 2006). Further studies have shown that SERT may also be inhibited at the posttranslational stage, likely through multiple binding sites on the SERT molecule itself (Henry *et al.* 2006; Iceta *et al.* 2007).

Fluoxetine transiently inhibits dorsal raphe firing, decreases terminal autoreceptor function, and ultimately increases net serotonin synaptic transmission within hippocampal CA3 pyramidal cells (Blier *et al.* 1988). Electrophysiological studies indicate that most antidepressants enhance net serotonin transmission after chronic administration (Blier *et al.* 1990), albeit at different loci: the TCAs via enhanced sensitivity of postsynaptic 5-HT$_{1A}$ receptors, and the SSRIs (and MAO inhibitors [MAOIs]) via reduced sensitivity of somatodendritic (5-HT$_{1A}$) and terminal (serotonin$_{1D}$) autoreceptors. SSRIs and TCAs also exert an inhibitory effect on serotonin$_3$ receptors in a noncompetitive fashion (Eisensamer *et al.* 2003). These observations of different mechanisms may help explain why certain depressive symptoms that do not respond to one class of antidepressant respond to another class, and they may also explain the enhanced response to combinations of antidepressant agents.

Norepinephrine

Chronic administration of most somatic treatments for depression downregulates or reduces the density of a-adrenergic binding sites in the brain (Bergstrom and Kellar 1979). These treatments include traditional norepinephrine-specific and mixed uptake inhibitors (Charney *et al.* 1981). Results with the SSRIs have been less consistent (Johnson 1991). Fluoxetine induces a-adrenergic receptor downregulation and increases extracellular norepinephrine concentrations in the rat prefrontal cortex after acute systemic administration (Bymaster *et al.* 2002). Fluoxetine also potentiates the noradrenergic effects of bupropion (Li *et al.* 2002).

Most studies with SSRIs have not shown a consistent change in b-adrenergic binding or b-adrenergic-stimulated cyclic adenosine monophosphate production. However, Baron *et al.* (1988) reported that fluoxetine, when coadministered with desipramine, augmented the reduction in cortical b-adrenergic receptors expected with desipramine alone. In contrast, investigations with fluvoxamine, paroxetine, and citalopram have not yielded consistent results. In general, the greater the serotonin selectivity of a compound, the less in vitro evidence for b-adrenergic downregulation has been seen. Thus, b-adrenergic downregulation may not be essential for clinical efficacy.

Current data do not support a significant SSRI effect on a-adrenergic receptor affinity or density, and studies of fluoxetine (Wong *et al.* 1985) have shown relative inactivity at this site. Fluoxetine reduces desipramine-induced release of growth hormone after 4 weeks of treatment (O'Flynn *et al.* 1991), suggesting possible indirect activity at the a_2-adrenergic receptor.

In summary, although relative differences in adrenoreceptor affinity exist across the SSRI class and fluoxetine may have more adrenergic activity than some of the other SSRIs, these differences appear to have negligible clinical significance.

Dopamine

Animal studies provide evidence that the serotonergic system may exert tonic inhibition on the central dopaminergic system. In rats, serotonin also decreases the generation of dopaminergic cells from mesencephalic precursors--an effect mediated by $serotonin_4$ and $serotonin_7$ receptors found on glial cells (Parga *et al.* 2007). Thus, fluoxetine might

diminish dopaminergic transmission, consistent with anecdotes of extrapyramidal side effects occurring during fluoxetine therapy (Bouchard *et al.* 1989). Serotonin agonists, however, also exert a facilitatory influence on dopamine release (Benloucif and Galloway 1991) that can be antagonized by the 5-HT_1 blocker pindolol, and evidence suggests that SSRIs may actually sensitize mesolimbic dopamine receptors (Arnt *et al.* 1984a, 1984b). Furthermore, repeated administration of fluoxetine, citalopram, or paroxetine to rats increased spontaneous dopaminergic neuronal activity (Sekine *et al.* 2007). Chronic fluoxetine treatment also increased brain-derived neurotrophic factor (BDNF) expression in rat dopaminergic regions (Molteni *et al.* 2006).

Summary of Neurotransmitter Effects

Fluoxetine enhances central serotonin transmission through increased output and/or increased postsynaptic receptor sensitivity (Blier *et al.* 1987). Fluoxetine's overall influences on the noradrenergic and dopaminergic systems are less straightforward and less likely to play a role in the drug's antidepressant effects. However, clinical response in depression remains highly individualized and is not guaranteed by such changes in any of the neurotransmitter systems (Charney *et al.* 1984).

Formulations

Fluoxetine is available in the United States in immediate-release tablet, capsule, and oral solution formulations. There is also a 90-mg capsule containing delayed-release pellets, which is taken once weekly. This formulation is not bioequivalent with the immediate-release products, and it has separate dosing and administration instructions. The less frequently used formulations (e.g., solution and delayed-release capsule) may be subject to drug shortages, given that there are fewer suppliers of these formulations (U.S. Food and Drug Administration 2023).

A capsule formulation that combines fluoxetine with olanzapine is also available in multiple strengths.

Pharmacokinetics and Disposition

Considerable pharmacokinetic variability exists within the SSRI class (Leonard 1992). Moreover, discussion of drug half-life must also include consideration of any active metabolites. Fluoxetine is extensively metabolized by the liver's cytochrome P450 (CYP) system to its active metabolite, norfluoxetine. Fluoxetine is a potent CYP2D6 inhibitor; norfluoxetine has a moderate inhibitory effect on CYP3A4 (Hemeryck and Belpaire 2002). The elimination half-life of norfluoxetine (4-16 days) is significantly longer than that of fluoxetine (4-6 days); in fact, norfluoxetine's half-life is the longest of any of the SSRIs or their active metabolites. Half-life is not significantly affected by hemodialysis or renal impairment (Aronoff *et al.* 1984).

Fluoxetine's relatively long half-life confers greater protection from the discontinuation syndrome associated with abrupt stopping of or noncompliance with treatment. However, more prolonged vigilance is required for drug-drug interactions after fluoxetine discontinuation; for example, a 5-week washout from fluoxetine is recommended before initiating an MAOI (Ciraulo and Shader 1990; Lane and Baldwin 1997). Variability in drug half-life is associated with a range in time to steady-state plasma concentration, which does not clearly predict or correlate with onset of antidepressant activity.

Mechanism of Action

In the absence of pharmacological manipulation, the reuptake of serotonin into the presynaptic nerve terminal typically leads to its inactivation. Fluoxetine, by blocking the reuptake process, acutely enhances serotonergic neurotransmission by permitting serotonin to act for an extended period at synaptic binding sites. The net result is an acute increase in synaptic serotonin. One difference separating SSRIs from direct-acting agonists is that SSRIs are dependent on neuronal release of serotonin for their action--that is, they are not direct stimulators of postsynaptic receptor function and depend on presynaptic neuronal integrity. These pharmacodynamic features might explain SSRI nonresponse. If the release of serotonin from presynaptic neuronal storage sites was substantially compromised and, in turn, if the net synaptic serotonin concentration was negligible, a clinically meaningful response to an SSRI would not be expected.

Serotonin receptors also include a family of presynaptic autoreceptors that suppress the further release of serotonin, thus limiting postsynaptic receptor stimulation. de Montigny *et al.* (1989) suggested that the enhanced efficacy of serotonergic synaptic transmission is not the result of increased postsynaptic sensitivity. Rather, longer-term SSRI treatment induced a desensitization of somatodendritic and terminal serotonin autoreceptors. This desensitization would permit serotonin neurons to reestablish a normal rate of firing, despite sustained reuptake blockade. These neurons could then release a greater amount of serotonin into the synaptic cleft. This modification reportedly occurs over a time course that is compatible with the antidepressant response.

A newer theory of the mechanism of action of fluoxetine and other antidepressants (including other SSRIs, TCAs, MAOIs, ketamine, and esketamine) posits that the key to their efficacy is their ability to bind to the transmembrane domain of tyrosine kinase receptor 2 (TRKB) and thereby enhance the presence of TRKB at the neuronal membrane surface (Casarotto *et al.* 2021). This theory is based on what is known about the neurochemical actions of antidepressants and the investigators' findings in cultured neurons and in rodent behavioral testing. Casarotto *et al.* (2021) noted that antidepressants promote TRKB signaling, which in turn facilitates BDNF-induced neuronal plasticity. The authors demonstrated that fluoxetine (and imipramine, venlafaxine, moclobemide, ketamine, and esketamine) increased the surface expression of TRKB in cortical neurons. Casarotto and colleagues next demonstrated that the binding of fluoxetine (and other drugs) to TRKB influenced rodent learning and behaviors that are dependent on neuronal plasticity. Increased neuronal plasticity is known to produce the rewiring of abnormally wired networks that is required for all antidepressants' therapeutic effects. The authors hypothesized that the delay in therapeutic responses to SSRIs and TCAs is due to their gradual attainment of effective levels in brain, whereas ketamine readily penetrates the brain and quickly achieves synaptic concentrations sufficient to promote TRKB stimulation of BDNF-induced neuronal plasticity and circuit rewiring.

Indications and Efficacy

The FDA-labeled indications for fluoxetine are major depressive disorder, OCD, panic disorder, bulimia nervosa, and premenstrual dysphoric disorder.

We review these disorders as well as others for which fluoxetine is commonly used. Of note for adult patients, fluoxetine in combination with olanzapine is approved for acute treatment both of depressive episodes associated with bipolar I disorder and of treatment-resistant depression (Eli Lilly 2011).

Major Depressive Disorder

Placebo-controlled, double-blind trials have established the superiority of fluoxetine over placebo in the treatment of depression (Kasper *et al.* 1992). Statistically significant reductions in Hamilton Rating Scale for Depression (Hamilton 1960) scores from baseline have been seen as early as the second week of treatment; however, the rate and the quality of response to any SSRI are highly individualized (range, 10-42 days). Overall, the efficacy of fluoxetine has been found to be comparable to or slightly better than that of the conventional TCAs (Cipriani *et al.* 2005; Wernicke *et al.* 1987) and comparable to that of venlafaxine (Nemeroff *et al.* 2007; Schatzberg and Roose 2006). Within the class of SSRIs, there is no clear and consistent evidence for superior effectiveness of one agent over others (Kroenke *et al.* 2001).

In general, the range for dosage titration with most SSRIs is relatively narrow, and higher dosages are more often associated with increased adverse events (Altamura *et al.* 1988; Amin *et al.* 1989). Schweizer *et al.* (1990) reported that in a study of 108 patients treated with fluoxetine 20 mg/day for 3 weeks and then randomly assigned to receive either 20 mg or 60 mg/day for another 5 weeks, both groups did equally well after 8 weeks.

Early implementation of high-dosage therapy may be appropriate in some circumstances. Conversion of nonresponders by prescribing at the higher end of the dosage range has been described with fluoxetine (Fava *et al.* 1992). Unfortunately, plasma-level studies have contributed little to the understanding of the dose-response relationship (Kelly *et al.* 1989), likely because plasma levels do not accurately reflect synaptic concentrations and/or pharmacodynamic effects.

Continued efficacy of fluoxetine during maintenance therapy has been established in several trials (Danion 1989; Dufour 1987; Ferrey *et al.* 1989; Montgomery *et al.* 1988; Reimherr *et al.* 1998). One trial reported recurrence for 54 of 94 individuals who received placebo (57%) versus 23 of 88 participants continued on fluoxetine maintenance (26%) ($P < 0.0001$) who had at least 4.5 months of recovery before randomization (Montgomery *et al.* 1988).

Although fluoxetine is perceived as "activating," several studies have demonstrated its efficacy in depression featuring anxiety and psychomotor agitation (Beasley *et al.* 1991; Jouvent *et al.* 1989; Montgomery 1989).

To improve compliance with long-term treatment, a once-weekly 90-mg oral formulation was developed (Schmidt *et al.* 2000), but it has not attracted widespread use.

Obsessive-Compulsive Disorder

Clomipramine, a potent inhibitor of both serotonin and norepinephrine reuptake, was observed more than 50 years ago to reduce obsessive-compulsive symptoms (Van Renynghe de Voxvrie 1968). The superior benefit of this potent serotonergic TCA over desipramine represents a cornerstone in the serotonin hypothesis of OCD (Benkelfat *et al.* 1989). Fluoxetine is effective for OCD independent of a patient's comorbid

mood status (Jenike *et al.* 1989). For response to occur, patients with OCD may require higher dosages of medication and longer treatment periods than do patients with depression. Most patients do not experience substantial relief sooner than 4-6 weeks into a trial, and it may take 10-12 weeks for this to occur. In the American Psychiatric Association's *Practice Guideline for the Treatment of Patients With Obsessive-Compulsive Disorder*, Koran *et al.* (2007) note that fluoxetine dosages up to 120 mg/day may occasionally be required and recommend that treatment continue for 1-2 years before a gradual taper is attempted. Currently, the SSRIs are considered a first-line treatment for OCD (Koran and Simpson 2013; Koran *et al.* 2007).

Fluoxetine has shown efficacy in children and adolescents with OCD, according to a meta-analysis of four randomized controlled trials (RCTs) (Maneeton *et al.* 2020). In addition, fluoxetine may be beneficial in some OCD spectrum disorders (placed in a separate chapter in DSM-5 [American Psychiatric Association 2013]), according to small controlled trials in excoriation disorder (Bloch *et al.* 2001; Simeon *et al.* 1997) and body dysmorphic disorder (Phillips *et al.* 2002).

Panic Disorder

SSRIs are the drugs of choice in the treatment of panic disorder and the prevention of panic attacks. Positive results from double-blind, placebo-controlled trials in patients with panic disorder are available for fluoxetine 10 and 20 mg/day (Michelson *et al.* 2001) and, in a 12-month SSRI comparison study, at a mean dosage of 27.8 mg/day (Dannon *et al.* 2007). In the long-term study, patients who continued their assigned SSRI had an excellent outcome (Dannon *et al.* 2007). Typically, a low dosage is used initially to minimize early side effects for patients with anxiety who are particularly sensitive to the disorder's somatic symptoms, and it sets the stage for long-term compliance.

Eating Disorders

Manipulation of central serotonin results in altered feeding behaviors (e.g., an increased satiety response) (Carruba *et al.* 1986). Blundell (1986) reported that pharmacological enhancement of serotonin reduced meal size, rate of eating, and body weight. The predominant locus of this serotonin effect is likely within the hypothalamus and may be mediated through gene expression of neuropeptide Y and proopiomelanocortin (Myung *et al.* 2005).

Bulimia nervosa. Clinical trials led the FDA to approve fluoxetine for the treatment of bulimia nervosa. Trials in which participants were administered fluoxetine 60 mg/day for 8 and 16 weeks showed a positive treatment effect on binge-eating and purging behaviors (Goldstein *et al.* 1995). A large double-blind, placebo-controlled 8-week study reported that fluoxetine 60 mg/day was more effective than 20 mg/day; the 20-mg dosage was more effective than placebo for only some outcomes (Fluoxetine Bulimia Nervosa Collaborative Study Group 1992). In a smaller study of 91 female patients in a primary care setting, those assigned to fluoxetine kept more physician appointments, exhibited greater reductions in binge eating and vomiting, and had greater improvement in psychological symptoms than those who received placebo (Walsh *et al.* 2004). Continued treatment with fluoxetine is associated with improvement and decreased risk of relapse (Romano *et al.* 2002).

Binge-eating disorder. Binge-eating disorder was officially listed with the Feeding and Eating Disorders in DSM-5. This disorder is characterized by recurrent binge-eating episodes, resultant marked distress, and absence of the compensatory behaviors seen in bulimia nervosa such as vomiting. In one RCT, fluoxetine was superior to placebo on some measures at 6 weeks (Arnold *et al.* 2002b), but in this and in a 16-week RCT (Grilo *et al.* 2005), fluoxetine was not associated at endpoint with superior binge-eating abstinence rates compared with placebo. In this trial, fluvoxamine was clearly inferior to cognitive-behavioral therapy (CBT) and did not enhance the outcome when added to CBT. Fluoxetine 60 mg/day far underperformed compared with CBT alone and did not improve outcome when added to CBT in two additional randomized trials (Grilo *et al.* 2012; Ricca *et al.* 2001), either at 24 weeks or at 1-year follow-up.

Anorexia nervosa. Pharmacological trials with SSRIs in patients with anorexia nervosa are less consistent. Kaye *et al.* (1991) suggested that fluoxetine may help maintain body weight in patients with anorexia nervosa who have gained weight. These investigators also completed a similar study with fluoxetine under controlled conditions, suggesting some benefit for fluoxetine in improving outcome and preventing relapse (Kaye *et al.* 2001). They reported that 10 of 16 patients given fluoxetine (target dosage of 60 mg/day) for 1 year had a significant reduction from baseline in measures of depression, anxiety, and OCD symptoms, whereas the 6 who discontinued did not. In a smaller 6-month follow-up study, the investigators found no benefit for these symptoms in 19 patients receiving an SSRI, of whom 7 received fluoxetine (Holtkamp *et al.* 2005). Walsh *et al.* (2006) found no benefit for continued treatment with fluoxetine after weight restoration in a double-blind RCT of 93 patients. The findings of all these studies are compromised by study participation refusal among eligible participants, small sample sizes, and high dropout rates.

Obesity. SSRIs have been extensively investigated for an effect on food consumption. This interest stems from evidence that perturbation of serotonin receptors modifies animal feeding behavior (Garattini *et al.* 1986). Serotonin innervation to the hypothalamus influences satiety and may selectively affect carbohydrate consumption (Wurtman *et al.* 1981). In one obesity treatment trial, 458 participants were administered fluoxetine (60 mg/day) or placebo for 52 weeks (Goldstein *et al.* 1994). Weight loss was significantly greater in the fluoxetine-treated group at 28 weeks but not at 52 weeks. In a randomized blinded study of children and adolescents, the effect on BMI was not greater at 12 or 24 weeks in the group randomly assigned to metformin plus fluoxetine (20 mg/day) than in those receiving metformin alone (Rezvanian *et al.* 2010). Long-term benefits may be better sustained when fluoxetine is combined with behavior modification (Marcus *et al.* 1990).

Premenstrual Dysphoric Disorder

Several blinded RCTs have established the efficacy and tolerability of fluoxetine in the treatment of premenstrual dysphoric disorder (Menkes *et al.* 1993; Pearlstein *et al.* 1997; Steiner *et al.* 1995; Su *et al.* 1993, 1997; Wood *et al.* 1992). In the largest study, 313 women with DSM-III-R late-luteal-phase dysphoric disorder (American Psychiatric Association 1987) received fluoxetine 20 mg/day, fluoxetine 60 mg/day, or placebo for six menstrual cycles after a two-cycle placebo washout period (Steiner *et al.* 1995). A total of 180 women completed the study. Both dosages of fluoxetine were superior

to placebo beginning at the first menstrual cycle and continuing throughout the six cycles. More patients treated with the 60-mg/day fluoxetine dosage discontinued because of adverse events compared with those administered

20 mg/day or placebo. More patients treated with placebo discontinued because of lack of response than did patients treated with either fluoxetine dosage. In a subsequent study of 34 women, fluoxetine was significantly superior to bupropion and placebo in treating premenstrual dysphoric disorder (Pearlstein *et al.* 1997). In a double-blind RCT of fluoxetine (10 or 20 mg/day) during the 14-day luteal phase, the 20-mg/day dosage but not the 10-mg/day dosage showed a significant advantage over placebo for the mood, physical, and social functioning symptoms of premenstrual dysphoric disorder; the 10-mg/day dosage was effective only for the mood symptoms (Cohen *et al.* 2002). A second luteal-phase study reported that fluoxetine 90 mg (e.g., a 90-mg controlled-release capsule taken once weekly) given 2 weeks and 1 week before expected menses was superior both to placebo and to 90 mg given 1 week before in improving measures of mood and social functioning but not physical symptoms (Miner *et al.* 2002).

Anger and Aggression

Diminished serotonergic activity has been implicated in impulsivity, anger, hostility, and aggression (Coccaro *et al.* 1989)--traits that are often encountered in Cluster B personality disorders (American Psychiatric Association 1994). Fluoxetine reduced impulsivity in small groups of patients with borderline personality disorder (Cornelius *et al.* 1991; Norden 1989). In two unpublished studies, however, fluoxetine (40 and 80 mg/day) was significantly less effective than dialectical behavior therapy in preventing suicide attempts within 6 or 12 months (Stoffers-Winterling *et al.* 2020). Fluoxetine significantly reduced the frequency of anger attacks in patients with and without depression; a dosage of 20 mg/day reduced the number of attacks to zero for more than two-thirds of patients with depression by 8 weeks (Fava *et al.* 1991, 1993, 1996; Rubey *et al.* 1996; Salzman *et al.* 1995).

Posttraumatic Stress Disorder

Fluoxetine significantly reduced symptoms of PTSD compared with placebo in 64 patients (veterans and nonveterans), as measured by the

Clinician-Administered PTSD Scale (van der Kolk *et al.* 1994). This medication also showed efficacy by week 6 in a large double-blind, placebo-controlled trial (Martenyi *et al.* 2002). However, the therapeutic effects of fluoxetine (and other SSRIs) are small compared with those of trauma-focused psychotherapies (Lee *et al.* 2016).

Premature (Early) Ejaculation

SSRIs, including fluoxetine, are effective in the treatment of premature ejaculation (Siroosbakht *et al.* 2019). Patients who do not respond to one SSRI (e.g., fluoxetine) often respond to another (Dadfar and Baghinia 2010; Murat Basar *et al.* 1999). In a 1-year follow-up study, patients treated with fluoxetine (20 mg/day or less) in combination with sexual behavior therapy reported significant improvement in ejaculation latency (Graziottin *et al.* 1996). Another study demonstrated efficacy from fluoxetine 90 mg administered weekly (Manasia *et al.* 2003).

Pain Syndromes

Fluoxetine has shown efficacy in reducing pain associated with diabetic neuropathy (Max *et al.* 1992) and fibromyalgia (Arnold *et al.* 2002a; Goldenberg *et al.* 1996). In addition, in two modest-sized, double-blind, placebo-controlled migraine headache trials (d'Amato *et al.* 1999; Saper *et al.* 1994), fluoxetine had a modest effect on overall headache status and total pain index scores after 2-3 months. Subsequent work demonstrated that antidepressants that also affect the norepinephrine system (i.e., serotonin-norepinephrine reuptake inhibitors) are more effective than the SSRIs in treating neuropathic pain (Mochizucki 2004; Pedersen *et al.* 2005).

Alcohol Use Disorder

A substantial amount of evidence from animal studies supports a serotonin dysfunction in alcohol abuse and dependence (Farren 1995). Although results are inconsistent, some clinical trials with SSRIs have reported reduced alcohol consumption in patients with and without depression in contrast with patients treated with TCAs, which have less robust efficacy (Cornelius *et al.* 1997; Lejoyeux 1996). However, a small 4-week double-blind study of fluoxetine (40 and 60 mg/day) reported no greater effect on alcohol intake than placebo (Naranjo *et al.* 1990). A 12-week, double-blind, placebo-controlled trial of fluoxetine in adolescents with alcohol use disorder and comorbid major depressive disorder found no difference from placebo in alcohol-or depression-related outcome variables (Cornelius *et al.* 2009). From a risk-benefit perspective, it is reassuring that fluoxetine does not appear to carry a high risk of fatal poisoning when taken in combination with alcohol (Koski *et al.* 2005).

Other Medical Conditions

Preliminary data support the efficacy of fluoxetine for patients who develop depression poststroke or after a cancer diagnosis. A 12-week double-blind RCT reported that early fluoxetine treatment of poststroke depression was more effective than placebo; open-label continuation treatment was more effective at 18 months of follow-up (Fruehwald *et al.* 2003). In a very large double-blind British RCT of patients with a clinical stroke diagnosis, investigators found that those assigned to fluoxetine were less likely to develop new depression at 6 months but had more bone fractures. Functional outcomes did not differ between the fluoxetine-and placebo-treated patients at 6 or 12 months (FOCUS Trial Collaboration 2019). A parallel study conducted in Sweden reported a similar result at 6 months (Lundstrom *et al.* 2020).

In one study, fluoxetine was not effective in treating postmenopausal hot flashes (Suvanto-Luukkonen *et al.* 2005). In a critical analysis, however, Loprinzi *et al.* (2009) pointed out that Suvanto-Luukkonen *et al.* (2005) did not use a no-treatment baseline measure, whereas two studies that did showed a positive effect of treatment.

At 6-month evaluation, fluoxetine was more effective than placebo in improving quality of life and reducing depressive symptoms in patients with early-stage breast cancer screened for depression (Navari *et al.* 2008). Fluoxetine's strong inhibition of CYP2D6 could, however, interfere with tamoxifen chemotherapy.

Two RCTs (Herscu *et al.* 2020; Reddihough *et al.* 2019) reported that fluoxetine and placebo had a similar effect on repetitive behaviors in children with autism spectrum disorder. A placebo-controlled pilot study of Crohn's disease also found no benefit from fluoxetine (Mikocka-Walus *et al.* 2017). Interestingly, fluoxetine may possess antiviral properties (Zuo *et al.* 2012). Two double-blind RCTs (Vercoulen *et al.* 1996; Wearden *et al.* 1998) of chronic fatigue syndrome found no greater effect from fluoxetine than placebo.

Side Effects and Toxicology

For most patients, SSRIs, including fluoxetine, are better tolerated than TCAs based on the number of early trial discontinuations attributable to an adverse event (see Boyer and Feighner 1991). For three-arm trials, the incidence of early discontinuation due to an adverse event was generally 5%-10% for placebo, 10%-20% for SSRIs, and 30%-35% for TCAs. The SSRIs, presumably by enhancing serotonin within the CNS, may induce agitation, anxiety, sleep disturbance, tremor, sexual dysfunction (primarily anorgasmia), or headache.

Because the enteric nervous system is richly innervated by serotonin, adverse events may include altered gastrointestinal motility and nausea. Certain autonomic adverse events, including dry mouth, sweating, and weight change, also occur. Furthermore, the use of SSRIs (including fluoxetine) during the perioperative period has been associated with a higher risk of adverse events, particularly bleeding events; however, the extent to which patient factors (e.g., medical illness) as opposed to the SSRIs themselves are responsible for the elevated risks remains unknown (Auerbach *et al.* 2013). Fluoxetine decreases rapid eye movement and increases non-rapid eye movement sleep at dosage ranges of 5-40 mg/kg in rodent models (Gao *et al.* 1992). This is a common property of many antidepressant medications.

As discussed earlier in this chapter, fluoxetine is unlikely to alter dopamine function. Nonetheless, some side effects, such as hyperprolactinemia, extrapyramidal symptoms, sexual and cognitive dysfunction, galactorrhea, mammary hypertrophy, and gynecomastia, have been attributed to the effects of SSRIs on the dopaminergic system (Damsa *et al.* 2004). Anecdotal reports of extrapyramidal side effects (Meltzer *et al.* 1979) associated with SSRIs are not more frequent than those reported historically with TCAs (Fann *et al.* 1976; Zubenko *et al.* 1987), MAOIs (Teusink *et al.* 1984), or trazodone (Papini *et al.* 1982). Very rare events, including arthralgia, lymphadenopathy, syndrome of inappropriate antidiuretic hormone secretion, agranulocytosis, and hypoglycemia, have been reported during clinical trials or postmarketing surveillance; however, causality typically is uncertain.

SSRIs, including fluoxetine, may increase the risk of bleeding if used concomitantly with antiplatelet drugs or anticoagulants. Some observational studies have found an association between SSRI use and bleeding complications (Auschra *et al.* 2022; Quinn *et al.* 2014).

One additional rare and life-threatening event associated with all SSRIs (and, more prominently, their interaction with MAOIs or other serotonin enhancers) is the central serotonin syndrome or *serotonin syndrome*. This phenomenon appears to represent an overactivation of central serotonin receptors and may manifest with features such as abdominal pain, diarrhea, sweating, fever, tachycardia, elevated blood pressure, altered mental state (e.g., delirium), myoclonus, increased motor activity, irritability, hostility, and mood change. Severe manifestations of this syndrome can induce hyperpyrexia, cardiovascular shock, or death. When a switch is being made from an SSRI to an MAOI, drug half-life (and that of any active metabolite, where applicable)

should serve as a guide to the length of the washout period. A standard recommendation is to wait at least five times the half-life of the SSRI or its metabolite, whichever is longer, before administering the next serotonergic agent (for a review, see Lane and Baldwin 1997). For fluoxetine, this means a minimum 5-week washout period.

Tolerance to an adverse event may change with dosage and/or length of exposure; higher dosages are typically associated with higher rates of adverse events (Bressa *et al.* 1989). Many events, such as activation (e.g., agitation, nervousness, insomnia), are typically transient (Beasley *et al.* 1991). Comparisons between morning and nighttime administration did not identify differences in efficacy (Usher *et al.* 1991).

In clinical trials, the incidence of increased heart rate or cardiac conduction disturbance has been very low with fluoxetine (Fisch 1985).

Suicidality

Evidence implicating serotonin depletion in suicide or violence is compelling. Reduced cerebrospinal fluid 5-hydroxyindoleacetic acid concentrations correlate highly with completed suicides in patients with depression (Edman *et al.* 1986; Ninan *et al.* 1984). In vitro binding assays have shown an increased density of 5-HT_2 receptors in individuals with depression and suicidal tendencies (Pandey *et al.* 1990). Both observations are consistent with a relative state of serotonin depletion among individuals with suicidal tendencies. The American College of Neuropsychopharmacology (1993) reviewed evidence showing that antidepressants result in substantial improvement or remission of suicidal ideation and impulses for the majority of patients; SSRIs were thought to potentially "carry a lower risk for suicide than older tricyclic antidepressants" (p. 181) when taken in overdose. Furthermore, the task force stated that no evidence indicated that SSRIs triggered emergent suicidal ideation above base rates associated with depression. In addition, Warshaw and Keller (1996) determined that fluoxetine use did not increase the rate of suicide in a group of 654 patients with anxiety disorders. In a large retrospective review of patients receiving one or more of 10 antidepressants (including fluoxetine), Jick *et al.* (1995) concluded that the risk for suicide was similar among all agents.

Concern about suicidality surged in 2003, after the industry alerted the FDA that there might be an increased risk of suicide-related adverse events in children treated with paroxetine. In its review of available data, the FDA found that approximately 4% of children taking SSRIs reported or exhibited suicidal thinking or behavior (including suicide attempts)--twice the rate of those taking placebo. No completed suicides occurred among nearly 2,200 children treated with SSRIs, however.

The FDA's review was followed by a number of other studies examining this issue, including a meta-analysis of 24 pediatric trials of nine antidepressant drugs (Hammad *et al.* 2006). The authors found a modestly increased risk of suicidality (risk ratio, 1.66) for SSRIs in antidepressant trials (95% CI, 1.02-2.68). This risk must be balanced against the benefit experienced by most patients with depression when they are given antidepressant therapy. In most cases, the therapeutic benefit of SSRIs will outweigh the risk of increased suicidal thoughts or behaviors (Bridge *et al.* 2007).

Black box warning. On March 22, 2004, the FDA issued a public health advisory warning of the risk of worsened depression and suicidality in children and adolescents being treated with antidepressant medications (Krause and Mehlinger 2005). This was followed by placement of a black box warning on the packaging of all antidepressant

medications, which was revised in 2006 to include adults through age 25 years. After the black box warning was placed, prescriptions for antidepressants decreased and suicide attempts in children and adolescents increased (Lu *et al.* 2014). A review of studies claiming that the black box warning led to more youth suicides concluded that these studies were methodologically weak and that the warning "is firmly rooted in solid data" (Spielmans *et al.* 2020). A commentary on this review suggested that the increased risk may have to do with incomplete maturation of the youthful brain. The commentary also noted that although the benefits of antidepressants outweigh the risks "for the majority of these patients . . . prescribers have a 'duty to warn' " (Goodman and Storch 2020).

Selective Serotonin Reuptake Inhibitor Discontinuation Syndrome

Discontinuation symptoms have been described with several classes of antidepressants. SSRI discontinuation symptoms have been reported least frequently with fluoxetine, mostly likely because of the long elimination half-lives of the parent compound and active metabolite (Haddad 1997; M.

M. S. Stahl *et al.* 1997). The most common physical symptoms are dizziness, nausea, vomiting, fatigue, lethargy, flulike symptoms (e.g., aches and chills), and sensory (e.g., paresthesia) and sleep disturbances. The most commonly reported psychological symptoms are anxiety, irritability, and crying spells. For most patients, the discontinuation symptoms are different from the adverse effects that they may have experienced while taking an SSRI. Discontinuation symptoms most often emerge within 1-3 days (Schatzberg *et al.* 1997).

Rosenbaum *et al.* (1998) compared the effects of a 5-to 8-day abrupt discontinuation period from fluoxetine, paroxetine, or sertraline in three groups of patients with depression receiving maintenance therapy. Patients in the paroxetine and sertraline groups had a significant increase in adverse events, whereas those in the fluoxetine group experienced no increase.

Consequently, SSRIs with short half-lives (paroxetine, citalopram, escitalopram, fluvoxamine) and related drugs, such as venlafaxine, should be tapered. Fluoxetine usually does not require tapering, given that plasma fluoxetine and norfluoxetine concentrations decrease gradually at the conclusion of therapy, which reduces the risk of discontinuation symptoms. However, if intolerable discontinuation symptoms do occur, resuming the previously prescribed dosage followed by a gradual dosage taper may be considered (Eli Lilly 1987).

Overdose

A major advantage of SSRIs has been their superior therapeutic index (Cooper 1988; Pedersen *et al.* 1982). The number of deaths per 1 million prescriptions across several SSRIs (range, 0-6) is substantially lower than that for conventional TCAs (range, 8-53) or MAOIs (range, 0-61) (Leonard 1992).

Borys *et al.* (1992) reported on 234 cases of fluoxetine overdose (serum level of 232-1,390 ng/mL). Fluoxetine was the sole ingestant in 87 cases; in the remaining 147 cases, it was taken in combination with alcohol and/or other drugs. Common symptoms included tachycardia, sedation, tremor, nausea, and emesis. The authors concluded that the emergent symptoms were minor and of short duration; thus, aggressive supportive care "is the only intervention necessary" (Borys *et al.* 1992, p. 115).

Drug-Drug Interactions

SSRIs are unlikely to be associated with many of the problems seen with the earlier antidepressants, including the cumulative CNS-depressant effects with alcohol, anticholinergic agents, or antihistaminic compounds. One potential for clinically relevant SSRI pharmacokinetic interactions is based on the drug effect on the CYP family of enzymes (Brosen and Gram 1989). For example, SSRIs are both substrates for and inhibitors of oxidation via CYP2D6. Crewe *et al.* (1992) ranked the potency of CYP2D6 inhibition for serotonergic antidepressants, revealing the most clinically relevant effects on CYP2D6 for paroxetine and fluoxetine.

Through inhibition of CYP2D6, fluoxetine may elevate the concentration of concomitantly administered drugs that rely on this enzyme for metabolism. This has particular clinical relevance when the second agent has a narrow therapeutic index. Examples of such agents include TCAs, several antipsychotics (particularly thioridazine, haloperidol, and clozapine), alprazolam, carbamazepine, flecainide, phenytoin, haloperidol, clozapine, quinidine, and propafenone (Rudorfer and Potter 1989), as well as other drugs metabolized by CYP2D6. The clinical consequence of such an interaction may either enhance or impair efficacy and/or heighten the adverse event profile. Fluoxetine should be used with caution in combination with drugs that cause QT prolongation, such as antibiotics (e.g., erythromycin and moxifloxacin), antiarrhythmic medications (e.g., quinidine and sotalol), and others (e.g., methadone, mefloquine, and tacrolimus).

The data with respect to fluoxetine's inhibition of other CYP enzymes, such as CYP3A3/4, CYP2C9, and CYP2C19, are less consistent, but the potential for such interaction exists.

Use in Pregnancy and Lactation

Published information about the use and safety of SSRIs in pregnancy and lactation is evolving. Goldstein *et al.* (1997) evaluated the outcomes of 796 prospectively identified pregnancies with confirmed first-trimester exposure to fluoxetine. Historical reports of newborn surveys were used for comparison. Abnormalities were observed in 5% of the fluoxetine-exposed newborns, which was consistent with rates in historical control subjects. In a review of studies published through 2012, the authors concluded that the small increase in the reported risk of cardiovascular malformation associated with fluoxetine in pregnancy was most likely attributable to ascertainment bias (Riggin *et al.* 2013). To aid in decision-making, Alwan *et al.* (2016) recommended offering ultrasound and fetal electrocardiography to all pregnant women taking an SSRI. In a 2017 review of the literature from 2005 to 2015 concerning psychopharmacotherapy in pregnancy and breastfeeding, the authors concluded that fluoxetine did not increase the risk of congenital malformations (Vitale *et al.* 2016). In a contemporaneous study of 16 cohort studies, Gao *et al.* (2017) concluded to the contrary that fluoxetine use during the first trimester was associated with "a slightly increased risk of cardiovascular malformations." However, investigators in a study of a large cohort of women exposed to an antidepressant in the year before pregnancy or during pregnancy found no increase in risk for major congenital malformation in the infants of those exposed to fluoxetine (Berard *et al.* 2017). An earlier review of the literature showed a statistically increased risk of persistent pulmonary hypertension of the newborn for infants exposed to SSRIs in late pregnancy, although clinically the absolute risk was low (Grigoriadis *et al.* 2014). The authors of a subsequent review agreed, but noted that rates of cardiovascular malformations did not differ from those seen in pregnancies of groups of mothers with depression or anxiety (Bandoli *et al.* 2020). In a review of meta-analyses of SSRI use in pregnancy, Uguz (2020) concluded, on the other hand, that the data consistently suggest that fluoxetine is associated with an increased risk of major congenital abnormalities. Given these varying reports, deriving in part from limited sample sizes, Dublin *et al.* (2020) called for new approaches to studying medication safety in pregnancy, including increased resources and collaborations that create larger databases to increase statistical power and the ability to reliably evaluate risks associated with individual drugs.

A longitudinal observational study reported no differences in growth variables (weight, length, and head circumference) from birth to age 12 months between infants exposed to SSRIs and those not exposed (Wisner *et al.* 2013). Pregnancy outcomes and follow-up cognitive and behavioral assessments for 135 children exposed in utero to a TCA or fluoxetine (55 infants) were compared with those for children in a control group of mother-infant pairs (Nulman *et al.* 1997). The incidence of major malformations and perinatal complications was similar among the three groups. No statistically significant differences in mean global IQ scores or language development were found in the children of mothers who received a TCA or fluoxetine compared with the children of control mothers. There were also no differences among the groups on several behavioral assessments. The results of children exposed during the first trimester were not different from those of children exposed throughout the pregnancy. A study failed to find a significant association between risk of autism spectrum disorder in offspring and maternal use of SSRIs--including fluoxetine--during pregnancy (Hviid *et al.* 2013).

Fluoxetine is secreted into breast milk (Hendrick *et al.* 2001). However, exposure of breastfeeding infants to fluoxetine is minimal, given the low concentrations and other factors, so the implications of this finding are unclear. Most of the available data (Burch and Wells 1992; Isenberg 1990; Taddio *et al.* 1996) suggested no adverse effects in exposed infants over the short period they were followed.

For women with depression responding to fluoxetine, the risks of discontinuing this medication or switching to a different antidepressant should be weighed against the risks of continuation. Risks associated with discontinuation include preterm birth, increased suicide attempts, decreased adherence to medical treatments, and decreased ability to care for the newborn.

Summary for Fluoxetine

Fluoxetine has been shown to be better tolerated than TCAs and to have a superior safety profile in overdose. Evidence suggests broad efficacy for fluoxetine across a spectrum of psychopathology.

Fluvoxamine

Fluvoxamine is a member of the SSRI family of drugs. This medication was initially manufactured in the United Kingdom in 1971. Fluvoxamine was registered as an antidepressant in Switzerland in 1983, becoming the first drug in the SSRI class to reach the market. Since its introduction, fluvoxamine has undergone a wide range of efficacy trials in depression, several anxiety disorders, and OCD. Fluvoxamine has been available in the United States since 1994, when the FDA approved it for the treatment of OCD (Ware 1997).

Structure-Activity Relations

Fluvoxamine belongs to the 2-aminoethyl oxime ethers of the aralkyl ketones (Figure 12-2) and is chemically identified as 5-methoxy-4'-(trifluoromethyl) valerophenone-(E)-O-(2-aminoethyl) oxime maleate (1:1). Fluvoxamine's empirical formula is $C_{15}H_{21}O_2N_2F_3*C_4H_4O_4$, and it does not have a chiral center or exist in stereoisomers. Because of local irritant properties, fluvoxamine cannot be administered parenterally (Physicians' Desk Reference 2015).

Mechanism of Action

Like other SSRIs, fluvoxamine binds to the presynaptic SERT and prevents it from reabsorbing serotonin into the presynaptic terminals, which increases the amount of serotonin in the synaptic cleft. How this translates into efficacy has been hypothesized to involve 5-HT_{1A} autoreceptor desensitization (Stahl 1998), increased sensitivity of $dopamine_2$-like receptors in the nucleus accumbens (Gershon *et al.* 2007), enhanced neurogenesis (Dranovsky and Hen 2006), changes in mitochondrial adenosine triphosphate levels (Ferreira *et al.* 2014), and individual pharmacogenomics factors involving SERT and catechol O-methyltransferase gene variants (Fukui *et al.* 2014; Mancama and Kerwin 2003). Furthermore, sigma-1 receptors seem to modulate several neurotransmitter pathways, and evidence suggests that fluvoxamine's affinity for the sigma-1 receptor exceeds that of all other SSRIs (Ishikawa *et al.* 2007).

Like fluoxetine, fluvoxamine's mechanism of action may involve its ability to bind to the transmembrane domain of tyrosine kinase receptor 2 (TRKB) to promote TRKB stimulation of BDNF-induced neuronal plasticity and circuit rewiring (Hashimoto 2013).

Pharmacological Profile

Fluvoxamine is a more potent inhibitor of serotonin reuptake than the TCAs, including clomipramine, but is less potent than the other SSRIs. It is highly selective for the serotonin transporter (inhibition constant $[K_i] = 2.3$ nmol/L) and has minimal affinity for the norepinephrine and dopamine transporters or the muscarinic, a_1-adrenergic, histaminic, and serotonin$_{2C}$ receptors. It possesses no MAO-inhibiting properties (Lapierre *et al.* 1983; Owens *et al.* 2001; Palmer and Benfield 1994; Ware 1997).

Formulations

In the United States, fluvoxamine formulations include immediate-release tablets and extended-release capsules in multiple strengths (U.S. Food and Drug Administration 2023).

Pharmacokinetics and Disposition

Fluvoxamine is almost entirely absorbed from the gastrointestinal tract, regardless of the presence of food (van Harten 1995). Still, first-pass metabolism limits oral bioavailability to 53% (DeVane 2003; DeVane and Gill 1997). Peak plasma concentrations occur within 2-8 hours, and steady-state concentration is achieved within 10 days (van Harten 1995). Plasma concentration shows no consistent correlation with efficacy or side effects, limiting the value of monitoring concentration.

The mean half-life of fluvoxamine is 15 hours, making twice-daily dosing preferable. Despite fluvoxamine's relatively short half-life, discontinuation syndrome is rare (Buchberger and Wagner 2002), possibly because of the drug's slower elimination from the brain (Strauss *et al.* 1998).

Because fluvoxamine is widely distributed and reaches higher concentrations in the brain and other organs than in plasma (Benfield and Ward 1986), patients receiving hemodialysis do not require replacement dosages; reequilibration should occur (DeVane and Gill 1997).

Compared with other SSRIs, fluvoxamine's rate of protein binding is relatively low (77%) (DeVane and Gill 1997), implying less risk of interactions from drug displacement.

At least 11 products of fluvoxamine metabolism are known, but none seem pharmacologically active (DeVane and Gill 1997; Palmer and Benfield 1994). Metabolism is thought to occur primarily through oxidative demethylation. Only minimal amounts of fluvoxamine (3%) are excreted unchanged by the kidneys (van Harten 1995).

Because hepatic clearance is decreased in elderly persons and individuals with liver disease, dosage adjustments may be necessary (DeVane and Gill 1997; van Harten *et al.* 1993). No biological sex-based differences in concentration seem to exist in adults (DeVane and Gill 1997). Studies in children report a higher area under the curve than in adolescents, especially in female individuals, suggesting that lower dosages may be sufficient. No appreciable pharmacokinetic differences between adolescents and adults have been observed (Physicians' Desk Reference 2015).

Indications and Efficacy

Depression

The first trial of fluvoxamine treatment for depression occurred in 1976. Since then, several single-or double-blind RCTs have tested fluvoxamine's antidepressant efficacy against placebo, SSRIs, serotonin-norepinephrine reuptake inhibitors, TCAs, tetracyclic antidepressants, and a reversible MAOI. Although the trials varied in design, the results taken together support the efficacy and safety of fluvoxamine in treating depression (including psychotic depression) across all age groups (Fukuchi and Kanemoto 2002; Haffmans *et al.* 1996; Kiev and Feiger 1997; Otsubo *et al.* 2005; Rapaport *et al.* 1996; Rossini *et al.* 2005; Ware 1997; Zanardi *et al.* 2000; Zohar *et al.* 2003).

Study durations ranged from 4 to 7 weeks, and dosages ranged from 50 to 300 mg/day. Furthermore, benefits from fluvoxamine seem to be sustained over at least 1 year (Terra and Montgomery 1998).

In an analysis of 54 RCTs ($N = 5{,}122$), researchers found no strong evidence to indicate that fluvoxamine was either superior or inferior to other antidepressants regarding response and remission (Omori *et al.* 2010). However, nausea and vomiting were reported more frequently with fluvoxamine compared with some other antidepressants.

Finally, because of its potent sigma-1 receptor agonism and the putative antipsychotic property such action might confer, it has been suggested that fluvoxamine monotherapy might be useful in treating psychotic depression (Furuse and Hashimoto 2009).

Panic Disorder

The largest double-blind RCT of fluvoxamine in panic disorder to date involved 188 participants assigned to 8 weeks of fluvoxamine treatment (100-300 mg/day) or placebo. At study end, significantly more individuals in the fluvoxamine group were free from panic attacks (69% vs. 46%; $P = 0.002$) (Figgitt and McClellan 2000).

Limited data suggest similar efficacy for fluvoxamine and the TCA imipramine as well as a possible potentiating effect of fluvoxamine when combined with cognitive or exposure therapy (Figgitt and McClellan 2000).

Social Anxiety Disorder

Liu *et al.* (2018) performed a meta-analysis of five RCTs that tested fluvoxamine in social anxiety disorder. They found significantly greater mean changes in Liebowitz Social Anxiety Scale scores (mean difference, 11.90; 95% CI, 8.09-15.71; $P < 0.001$) and Clinical Global Impression Scale severity of illness scores (mean difference, 0.52; 95% CI, 0.33-0.72; $P < 0.001$) among participants assigned to fluvoxamine compared with placebo, but with a higher incidence of treatment-emergent adverse events (OR, 2.66) (Liu *et al.* 2018).

Obsessive-Compulsive and Related Disorders

Obsessive-compulsive disorder in adults. The first formal test of fluvoxamine in OCD occurred in 1987 (Price *et al.* 1987). Since then, multiple randomized studies have established fluvoxamine's efficacy and safety in treating OCD. These trials have compared fluvoxamine with placebo, clomipramine, and other SSRIs.

In randomized double-blind comparisons with placebo, participants were given fluvoxamine 100-300 mg/day for 6-10 weeks. Significant improvements in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores were observed, and response rates ranged from 38% to 52% for fluvoxamine versus 0% to 18% for placebo (Figgitt and McClellan 2000).

Five double-blind comparisons of fluvoxamine and clomipramine, both dosed at 300 mg/day or less (Figgitt and McClellan 2000; Freeman *et al.* 1994; Koran *et al.* 1996; Milanfranchi *et al.* 1997; Mundo *et al.* 2000, 2001), demonstrated equal efficacy, with response rates of 56%-85% for fluvoxamine and 53%-83% for clomipramine. The results of a 10-week single-blind study of 30 participants randomly assigned to fluvoxamine, paroxetine, or citalopram suggested similar efficacy (Mundo *et al.* 1997).

Long-term maintenance treatment with fluvoxamine seems to protect against relapse. In a 2-year open-label follow-up study, Ravizza *et al.* (1996) enrolled 130 individuals who had responded to fluvoxamine 300 mg/day, clomipramine 150 mg/day, or fluoxetine 40 mg/day. Maintenance treatment at full or half dosages was significantly superior in preventing relapse compared with treatment discontinuation (Ravizza *et al.* 1996).

Predictors of response to fluvoxamine in OCD were evaluated in a study involving 17 individuals who underwent functional MRI at baseline and after 12 weeks of treatment (final dosage, 200 mg/day). Pretreatment hyperactivation of the right cerebellum and left superior temporal gyrus was associated with reduced Y-BOCS scores posttreatment (Sanematsu *et al.* 2010).

Another study investigated treatment compliance with fluvoxamine and cognitive therapy. Forty-eight individuals with OCD who did not respond to behavioral therapy were randomly assigned to 12 weeks of either fluvoxamine ($n = 26$) or cognitive therapy ($n = 22$). Although a higher baseline Y-BOCS score and assignment to cognitive therapy were associated with better compliance, the fluvoxamine group demonstrated statistically superior improvement compared with the cognitive therapy group (Landsheer *et al.* 2015).

In a recent study, Zheng *et al.* (2019) tested augmentation with methylphenidate as a means of improving response to fluvoxamine in OCD. Forty-four participants were randomly assigned to fluvoxamine (250 mg/day) given with extended-release methylphenidate (36 mg/day) or with placebo. A significantly higher reduction in Y-BOCS score was seen for the fluvoxamine group ($P < 0.001$) (Zheng *et al.* 2019).

Obsessive-compulsive disorder in children and adolescents. Fluvoxamine (50-200 mg/day) was tested in a 10-week, double-blind, placebo-controlled study involving 120 participants ages 8-17 years with OCD. Response was defined as a reduction of at least 25% in Children's Y-BOCS scores. Mean scores were significantly lower in the fluvoxamine group as early as week 1 ($P < 0.05$). End-of-study response rates were 42% for the fluvoxamine group and 26% for the placebo group ($P = 0.065$). The most common side effects were insomnia and asthenia (Riddle *et al.* 2001).

Other obsessive-compulsive and related disorders. Three open-label trials of fluvoxamine involving a total of 75 participants with body dysmorphic disorder reported response rates of 63%-67% (Perugi *et al.* 1996; Phillips *et al.* 1998, 2001). A 12-week open-label study of fluvoxamine administered to 21 participants with trichotillomania produced only minor improvement (Stanley *et al.* 1997).

Other addictive or impulse-control disorders. Like other SSRIs, fluvoxamine has produced inconsistent results when tested in impulse-control disorders or behavioral addictions that are sometimes considered part of the obsessive-compulsive spectrum. Despite encouraging open-label data for individuals with compulsive buying disorder (Black *et al.* 1997), two double-blind, placebo-controlled studies failed to show benefit over placebo (Black *et al.* 2000; Ninan *et al.* 2000).

Similarly, two small studies of pathological gambling (DSM-IV [American Psychiatric Association 1994]) suggested that fluvoxamine might be beneficial (Hollander *et al.* 1998, 2000). However, a larger 6-month double-blind, placebo-controlled study failed to show separation from placebo (Blanco *et al.* 2002).

Posttraumatic Stress Disorder

Small open-label studies suggest a role for fluvoxamine in treating PTSD (Davidson *et al.* 1998; Figgitt and McClellan 2000; Marmar *et al.* 1996; Tucker *et al.* 2000). Twenty-four Dutch World War II veterans with chronic PTSD showed significant improvement on a PTSD self-rating scale after a 12-week course of fluvoxamine (300 mg/day or less; $P = 0.04$; De Boer *et al.* 1992). More recently, a 14-week open-label trial of fluvoxamine (100-300 mg/day) in 15 U.S. veterans with combat-related PTSD reported a statistically significant decrease in Clinician-Administered PTSD Scale total scores ($P < 0.001$) (Escalona *et al.* 2002).

Eating Disorders

In a study by Fichter *et al.* (1996), 72 individuals with bulimia nervosa who had been treated successfully with psychotherapy were randomly assigned to fluvoxamine (100-300 mg/day) or placebo and were followed for 12 weeks. Fluvoxamine was significantly superior in preventing relapse ($P < 0.05$) (Fichter *et al.* 1996). The results of a small 12-week double-blind, placebo-controlled study in 12 individuals with acute bulimia nervosa suggested that fluvoxamine 200 mg/day was superior to placebo (Milano *et al.* 2005).

In a 9-week double-blind, placebo-controlled study by Hudson *et al.* (1998) in 85 individuals with binge-eating disorder, the investigators found that fluvoxamine (50-300 mg/day) was significantly more effective than placebo in reducing binge frequency.

Delirium

Antipsychotic drugs have been widely used for treating delirium but are associated with sedation, extrapyramidal side effects, and cardiac arrhythmias. Furthermore, there is an elevated risk of mortality in older patients treated with atypical antipsychotics. The endoplasmic reticulum protein sigma-1 receptors are thought to play an important role in calcium signaling and cell survival, and they may regulate a number of neurotransmitter systems implicated in the pathophysiology of delirium. Preliminary studies suggested that fluvoxamine may be effective in treating delirium because of its sigma-1 receptor effects (Furuse and Hashimoto 2010a, 2010b, 2010c; Hashimoto 2015).

Pain

Preliminary research has explored the potential antipain properties of fluvoxamine. In an RCT of 120 individuals with cancer accompanied by moderate to severe pain, participants were assigned to flexibly dosed extended-release oxycodone either alone (*n* = 60) or in combination with fluvoxamine (150 mg/day or greater; *n* = 60). Individuals in the oxycodone-only group required maximum dosages of extended-release oxycodone at 54 and 132 mg/day for moderate and severe pain, respectively, compared with 44.7 and 110 mg/day for the combination group. Participants who received fluvoxamine augmentation required lower dosages of oxycodone, but the difference was statistically significant only for severe pain (Xiao *et al.* 2014).

COVID-19

Fluvoxamine stimulates the sigma-1 receptor involved in regulating cytokine production. A review of clinical trials concluded that fluvoxamine produces a clinically meaningful and statistically significant reduction in COVID-19-related morbidity and possibly mortality (Lenze *et al.* 2023). The review noted that observational studies suggested (but did not prove) that fluoxetine and other SSRIs also reduce COVID morbidity and mortality. The authors reported that psychotropic medications including fluoxetine and fluvoxamine are under study as anticancer drugs, and--as a result of their anti-inflammatory function--may prove useful in Alzheimer's disease and other neurodegenerative disorders, CNS amyloid deposition, macular degeneration, and other disorders involving inflammatory pathophysiology.

Side Effects and Toxicology

Data from 34,587 patients enrolled in postmarketing fluvoxamine studies were combined in a database to assess safety. Dosages ranged from 50 to 300 mg/day taken over 4-52 weeks (Wagner *et al.* 1994). Overall, 14% of participants discontinued treatment because of side effects--most frequently, nausea and vomiting (4.6% and 1.7%, respectively). The adverse events reported at greater than 5% incidence were nausea, somnolence, and asthenia (15.7%, 6.4%, and 5.1%, respectively). The rate of weight gain was only 1%. Sexual side effects were not mentioned (only side effects with greater than 1% incidence were listed), although a separate open-label study designed to assess SSRI-induced sexual dysfunction in men and women showed statistically similar rates for fluvoxamine, fluoxetine, sertraline, and paroxetine (range, 54.4%-64.7%) (Montejo-Gonzalez *et al.* 1997).

Another postmarketing surveillance review covering 17 years (Buchberger and Wagner 2002) analyzed 6,658 individual reports, including 16,110 adverse drug reactions. The frequency of death was calculated at 0.9 per 100,000 patients. Suicide, mostly by overdose, was the cause of death in nearly half, but only 1.2% of overdoses involved fluvoxamine alone. Drug interactions were reported at a rate of 0.85 cases per 100,000 patients, most commonly with clozapine. Cases of switch to mania and discontinuation syndrome were also rare, occurring at rates of 0.47 and 0.38 events per 100,000 patients, respectively. Serotonin syndrome was even less frequent.

A more recent study assessed the cardiac effects of fluvoxamine in beagle dogs (*n* = 4). Dogs were administered fluvoxamine 0.1 mg/kg intravenously, corresponding to the recommended daily oral dose, followed by second and third doses of 1 and 10 mg/kg, respectively. Both supratherapeutic doses were associated with QT interval prolongation (Yamazaki-Hashimoto *et al.* 2015).

In two studies, researchers found no consistent treatment-related changes in laboratory values or vital signs in fluvoxamine-exposed subjects (Wagner *et al.* 1994).

Liver test abnormalities have been reported to occur for up to 1% of patients taking fluvoxamine; the elevations are typically modest and discontinuation is not required (LiverTox 2023).

Drug-Drug Interactions

Fluvoxamine is a potent inhibitor of CYP1A2. Drugs partially metabolized by CYP1A2 whose levels may rise as a result of fluvoxamine's inhibition of this isozyme include tizanidine, tertiary-amine TCAs (imipramine, amitriptyline, and clomipramine), clozapine, tacrine, theophylline, propranolol, and caffeine. Dosages of theophylline and clozapine should be reduced if coadministered with fluvoxamine (DeVane and Gill 1997). Conversely, a review of data from 241 patients suggests that fluvoxamine coadministration can increase the probability of antipsychotic response in individuals who cannot achieve sufficient clozapine plasma levels (Polcwiartek and Nielsen 2016).

Fluvoxamine also inhibits CYP2C19 and CYP3A4. CYP2C19 metabolizes warfarin, and elevations in warfarin concentration have been reported in patients taking fluvoxamine. As a result, closer monitoring of anticoagulation status is indicated for these patients. Alprazolam and diazepam are metabolized in part through CYP3A4, and fluvoxamine has been shown to prolong their elimination (DeVane and Gill 1997). Carbamazepine is partially metabolized through CYP3A4, and elevated carbamazepine levels have been documented in patients concomitantly taking fluvoxamine (Palmer and Benfield 1994). Other drugs whose metabolism through CYP3A4 may be affected by fluvoxamine include pimozide, methadone, and thioridazine. Because of the serious QT interval prolongation that can occur when terfenadine or astemizole is combined with the potent CYP3A4 inhibitor ketoconazole, it is recommended that fluvoxamine be avoided in patients who require these antihistamines (DeVane and Gill 1997). Of note, terfenadine and astemizole are no longer commercially available in the United States (U.S. Food and Drug Administration 2023). Fluvoxamine is contraindicated for use with thioridazine, tizanidine, pimozide, alosetron, ramelteon, and MAOIs (Jazz Pharmaceuticals 2011).

Fluvoxamine drug interactions have also been reported with sumatriptan, tacrine, tryptophan, diltiazem, propranolol, and metoprolol (Jazz Pharmaceuticals 2011).

Use in Pregnancy and Lactation

Limited data are available to guide clinicians and patients on the use of fluvoxamine in pregnancy. One study aimed to assess teratogenic or perinatal effects relating to fluvoxamine exposure in utero in 92 pregnant women, 37 of whom were taking other medications concomitantly. No significant difference in adverse events was seen in the treatment group compared with the control group (Gentile 2005). The FDA lists fluvoxamine in Pregnancy Category C.

Very limited information is available on infants exposed to fluvoxamine during lactation (Gentile 2005). In the eight cases published, no adverse events were reported.

Summary for Fluvoxamine

Nearly four decades of research have established fluvoxamine as a generally well-tolerated medication with potential efficacy across a range of disorders. However, two factors may have prevented even more widespread use: drug-drug interactions, which make fluvoxamine a less attractive choice for some patients, and a perception, especially in the United States, that fluvoxamine is primarily an anti-OCD drug.

CHAPTER 13

Sertraline and Paroxetine

Jonathon R. Howlett, M.D.
Alan F. Schatzberg, M.D.

Sertraline and paroxetine are classified as selective serotonin reuptake inhibitors (SSRIs) because of their potent inhibition of presynaptic serotonin uptake. Initially approved for depression, both medications have proven effective for a wide array of psychiatric disorders. Sertraline has received FDA approval for the treatment of depression, OCD (adult and pediatric populations), PTSD, panic disorder, premenstrual dysphoric disorder, and social anxiety disorder. Paroxetine has received FDA approval for depression, panic disorder, social anxiety disorder, generalized anxiety disorder, OCD, PTSD, premenstrual dysphoric disorder, and vasomotor symptoms (hot flashes) associated with menopause. Like other SSRIs, sertraline and paroxetine are characterized by good tolerability profiles, increasing their usefulness in comparison with older antidepressants.

History and Discovery

The synthesis of the first SSRI, fluoxetine, in 1972 marked the inception of an exciting new era of scientific and clinical innovation in psychiatry (Wong *et al.* 1995). Prior to this discovery, psychiatrists had only a few classes of pharmacological treatments for managing depression and anxiety. These medication classes, including tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and benzodiazepines, were indeed efficacious; however, they were poorly tolerated and therefore quite limited in usefulness.

Shortly after the introduction of fluoxetine into the U.S. market in 1988, a marked increase in research led to the development of other SSRIs, which ultimately proved effective in a wide array of psychiatric disorders. In 1991, sertraline became the second SSRI to be approved by the FDA for the treatment of depression; the following year, paroxetine became the third SSRI to receive approval.

Sertraline is marketed as immediate-release tablets, higher-strength capsules, and an oral solution concentrate. Generic equivalent products are available for most dosage forms. The oral solution has been shown to be bioequivalent to the 20-mg tablet and may be useful for ease of administration and for tapering dosages of sertraline (van den Tweel *et al.* 2007). Paroxetine hydrochloride, originally marketed under the name Paxil, is available as immediate-release tablets, controlled-release tablets, and an oral suspension. Generic products are available for these dosage forms. Paroxetine is also marketed in a mesylate salt form as tablets and in a capsule formulation. These products are discussed in greater detail later in the chapter.

Structure-Activity Relations and Pharmacological Profile

Sertraline (Figure 13-1) and paroxetine (Figure 13-2) specifically block the reuptake of serotonin in the soma and terminal regions of serotonergic neurons. Serotonin neurons in the midbrain raphe nuclei have inhibitory autoreceptors in both the soma (serotonin$_{1A}$ [5-HT$_{1A}$] receptors) and terminal area (serotonin$_{1B}$ receptors) that are stimulated by the acute increase in serotonin. The immediate effect of serotonin transporter (5-HTT) blockade is to increase the amount of serotonin in axosomatic synapses and to decrease neuronal firing (Blier 2001; Blier *et al.* 1990;

Heym and Koe 1988). Over several weeks, these autoreceptors are desensitized and firing rates increase.

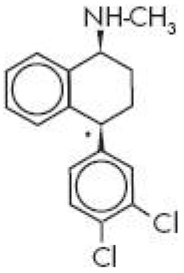

FIGURE 13-1. Chemical structure of sertraline.

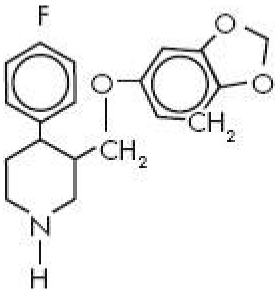

FIGURE 13-2. Chemical structure of paroxetine.

Among the various antidepressant agents that block 5-HTT, paroxetine and sertraline are the highest and second highest, respectively, in potency for serotonin reuptake blockade, as demonstrated in animal models (Hiemke and Hartter 2000; Owens *et al.* 2001; Richelson 1994). The selectivity of sertraline for norepinephrine follows that of escitalopram (Hiemke and Hartter 2000; Owens *et al.* 2001), although other work suggests greater selectivity for fluvoxamine than for sertraline (Richelson 1994). In contrast, paroxetine is the most potent inhibitor of the norepinephrine transporter among drugs classified as SSRIs, although paroxetine's norepinephrine transporter antagonism does not approach the magnitude of its 5-HTT antagonism (Finley 1994). Substantial norepinephrine transporter antagonism does occur at dosages of 40 mg/day

or greater for immediate-release paroxetine (Gilmor *et al.* 2002). The relative selectivity for 5-HTT, compared with the dopamine transporter, is lowest for sertraline, whereas paroxetine has low affinity for the dopamine transporter (Owens *et al.* 2001).

While sertraline has little appreciable antagonistic effect on muscarinic cholinergic receptors, the affinity of paroxetine for the muscarinic cholinergic receptor is similar to that of desipramine. Paroxetine is used at lower dosages than desipramine and is therefore less anticholinergic than this tricyclic agent. However, this property may account for paroxetine's mild anticholinergic side effects, including dry mouth, blurry vision, and constipation (Owens *et al.* 1997). Neither sertraline nor paroxetine exhibits appreciable affinity for histamine$_1$ receptors (Hiemke and Hartter 2000; Richelson 1994). The antagonism of a$_1$ adrenoreceptors by sertraline is at least 10-fold more potent than that of other SSRIs (Hiemke and Hartter 2000), although this antagonism does not translate into clinically meaningful hypotension or reflex tachycardia. However, a previous report suggested that sertraline decreases sympathetic nervous system activity, a property consistent with receptor blockade (Shores *et al.* 2001). It is also possible that the decrease in sympathetic response is related to stimulation of the 5-HT$_{1A}$ receptors noted earlier.

Sertraline is metabolized to desmethylsertraline (see the following section, "Pharmacokinetics and Disposition"). This compound is approximately one-tenth as active in blocking the reuptake of serotonin; it also lacks antidepressant activity in animal models (Heym and Koe 1988).

Sertraline exhibits inhibitory activity on several cytochrome P450 (CYP) enzymes. The ability of the compound to slightly elevate dextromethorphan and desipramine supports modest inhibition of CYP2D6 (Hiemke and Hartter 2000; Ozdemir *et al.* 1998; Preskorn 1996). It has little appreciable inhibition of CYP1A2, even when used at higher dosages (Ozdemir *et al.* 1998). A very mild elevation of CYP2C9/10 substrates has been found in several studies (Preskorn 1996). Sertraline has complex effects on the CYP3A3/4 enzyme system: it initially shows slight inhibition, but it also induces this system, albeit modestly, over time (Preskorn 1996). Paroxetine is the most potent inhibitor of the CYP2D6 enzyme system among the SSRIs (Crewe *et al.* 1992; Nemeroff *et al.* 1996), and its inhibition of CYP2D6 can continue for up to 5 days after discontinuation (Liston *et al.* 2002).

Pharmacokinetics and Disposition

Absorption and Distribution

Sertraline

Sertraline is absorbed slowly via the gastrointestinal tract, with peak plasma levels occurring between 6 and 8 hours after ingestion (Warrington 1991). The delay may be the result of enterohepatic circulation (Hiemke and Hartter 2000; van Harten 1993). Sertraline tablets may be taken with or without food (Pfizer 2021). The medication is more than 95% protein bound; however, because it binds weakly to a_1 glycoproteins, it does not cause substantial displacement of other protein-bound drugs (Preskorn 1996).

The volume of distribution of sertraline is large, exceeding 20 L/kg. The distribution is larger in young (18-45 years) female individuals than in young male individuals (Warrington 1991). In animal models, the concentration of sertraline is 40 times higher in brain than in plasma (Hiemke and Hartter 2000).

Paroxetine

Paroxetine is well absorbed from the alimentary tract, and absorption is not affected by the presence or absence of food (Kaye *et al.* 1989). Paroxetine is highly lipophilic and is readily distributed into peripheral tissues, with a high volume of distribution and 95% protein binding (Kaye *et al.* 1989). Oral bioavailability is affected by extensive first-pass metabolism (Lane 1996). With serial dosing, bioavailability increases as the hepatic metabolic system becomes saturated and a larger proportion of the parent compound enters the systemic circulation (Kaye *et al.* 1989). After oral dosing, steady-state concentrations of paroxetine exhibit wide intersubject variability (Sindrup *et al.* 1992a); however, there appears to be no relationship between paroxetine levels and clinical response or adverse outcomes (Tasker *et al.* 1989).

Metabolism and Elimination

Sertraline

The elimination half-life of sertraline is 26-32 hours, and steady-state levels are achieved after 7 days. Sertraline shows linear pharmacokinetics within a range of 50-200 mg/day (Warrington 1991) and does not appear to inhibit or induce its own metabolism. Peak plasma levels are somewhat lower in young male individuals than in young female, older female, or older male individuals (Ronfeld *et al.* 1997; Warrington 1991), and the elimination rate constant is higher in young (18-45 years) male individuals (0.031/hour) than in young female (0.022/hour) and older ([?] 65 years) female or male individuals (0.019/hour). Maximal plasma concentrations of sertraline may be significantly reduced after a gastric bypass procedure (Roerig *et al.* 2012).

In children between the ages of 6 and 17 years, weight-corrected metabolism is more rapid. The maximum concentration and the area under the curve are 22% lower in children than in adults. Despite this relatively more efficient metabolism, the smaller body mass of most children suggests that lower dosages of sertraline should be used in pediatric populations (Pfizer 2021).

Sertraline is metabolized in the liver via oxidative metabolism; the concentration of the primary metabolite, desmethylsertraline, is up to threefold higher than that of the parent compound (Hiemke *et al.* 1991; Ronfeld *et al.* 1997; Warrington 1991). Desmethylsertraline levels are also lower in young male individuals than in young female, elderly female, or elderly male individuals. The peak concentration of desmethylsertraline is attained more quickly in young female individuals (6 hours) than in young male, older female, and older male individuals (9, 8, and 14 hours, respectively) (Warrington 1991). The half-life of desmethylsertraline is 1.6-2.0 times that of the parent compound (Warrington 1991).

Whereas desmethylsertraline is the major metabolite of sertraline, other minor metabolites include a ketone and an alcohol compound (Warrington 1991). Less than 0.2% of an oral dose of sertraline is excreted unchanged in urine, whereas approximately 50% is found in feces. The enzymes involved in the metabolism of sertraline to desmethylsertraline remain unclear (Greenblatt *et al.* 1999). Although six different CYP enzymes have the capacity to catalyze this reaction, none account for more than 25% of sertraline's clearance. The contribution of each CYP enzyme is dependent not only on the protein's activity on the substrate, as evidenced through in vitro models, but also on the abundance of the enzyme. Given these properties, one computer model identified CYP2C9 as the greatest contributor (approximately 23%) to sertraline demethylation, with CYP3A4 and CYP2C19 each contributing about 15%, CYP2D6 adding 5%, and CYP2B6 contributing 2% to the process (Greenblatt *et al.* 1999; Lee *et al.* 1999). These percentages can vary across individuals, depending on the amount of available enzyme or enzyme inhibition that occurs. Because multiple CYP enzymes are involved in sertraline's metabolism, concurrent use of medications with specific CYP inhibition is unlikely to substantially impair the process (Greenblatt *et al.* 1999). However, increased CYP2B6 activity was seen in mice as a consequence of sertraline coadministration with bupropion (Molnari *et al.* 2012). A more recent study from Denmark reported that CYP2C19 also contributes to sertraline blood levels, and individuals who are slow metabolizers due to allelic variation may require dosage reductions in sertraline (Braten *et al.* 2020).

Patients with liver disease experience decreased sertraline metabolism (Hiemke and Hartter 2000). For individuals with mild liver impairment, the half-life of the drug may be increased threefold (Pfizer 2021), and concentrations are likely to be greater in patients with severe impairment. Although renal impairment does not appreciably influence the metabolism of sertraline (Hiemke and Hartter 2000), patients with severe end-stage renal disease undergoing hemodialysis do not appear to tolerate sertraline 25 mg/day without risk of significant toxicity (Chander *et al.* 2011).

Paroxetine

The average elimination half-life of paroxetine is approximately 21 hours (coefficient of variation [CV], 32%). Because of paroxetine's nonlinear pharmacokinetics (discussed later in chapter), time to steady state will vary among individuals. In repeat-dose studies in healthy volunteers, steady state was achieved within 2 weeks for both the immediate-release and the controlled-release dosage forms (GlaxoSmithKline 2019).

The rate-limiting step in the metabolism of paroxetine is the CYP2D6 enzyme system (Crewe *et al.* 1992; Sindrup *et al.* 1992a). Genetic studies have demonstrated as many as 40 polymorphisms of the CYP2D6 enzyme, which in part may explain the differences in pharmacokinetic parameters observed among individuals (Lane 1996). Individuals can be categorized by CYP2D6 phenotype as being poor, intermediate, extensive, or ultrarapid metabolizers, denoting that they have very high, high, low, or very low serum paroxetine concentrations, respectively (Charlier *et al.* 2003). Ultrarapid metabolizers may be at greater risk of antidepressant nonresponse, although this has not been clearly demonstrated, and paroxetine's minimum therapeutic concentration is not well defined. Similarly, a putative increased risk of adverse events for poor metabolizers has not been confirmed (Hicks *et al.* 2015). Patients with negligible or diminished CYP2D6 activity are thought to use alternative enzyme systems (Gunasekara *et al.* 1998; Lane 1996).

Given its potent inhibition of the CYP2D6 enzyme system (Crewe *et al.* 1992; Nemeroff *et al.* 1996), paroxetine is both a substrate and inhibitor of its own metabolism. Paroxetine therefore has a nonlinear pharmacokinetic profile, such that higher dosages produce disproportionately greater plasma drug concentrations as the enzyme becomes saturated (Preskorn 1993). With immediate-release paroxetine, peak plasma concentration is attained in approximately 5 hours, and plasma steady-state concentration is achieved within 4-14 days (Kaye *et al.* 1989). The terminal half-life of the parent compound is approximately 1 day and increases at higher dosages, consequent to autoinhibition of CYP2D6 (Preskorn 1993). The pharmacokinetic properties of paroxetine appear to be affected by age. Bayer *et al.* (1989) reported a threefold increase in maximum plasma concentration in elderly persons compared with younger individuals after a single dose of paroxetine. Furthermore, the terminal half-life in the elderly subgroup was extended by nearly 100%.

In individuals with renal impairment, both half-life and maximum plasma levels of paroxetine have been shown to increase relative to the extent of kidney disease (Doyle *et al.* 1989). In patients with severe liver disease, there are considerable elevations in the steady-state concentration and the terminal half-life of paroxetine (Dalhoff *et al.* 1991). Patients with substantial renal or hepatic impairment should initially receive lower paroxetine dosages to avoid potential side effects.

The controlled-release paroxetine formulation is designed to slow absorption and delay the release of paroxetine until after the tablet has passed through the stomach. With this formulation, 20% of the drug is excreted unchanged from the gastrointestinal tract, such that 20% higher dosages of controlled-release paroxetine are necessary to achieve the same bioavailability (DeVane 2003). Dissolution after single dosing takes 4-5 hours; otherwise, controlled-release paroxetine displays the same pharmacokinetic parameters as the immediate-release formulation with regard to terminal half-life and nonlinearity.

Paroxetine mesylate is marketed as a novel 7.5-mg capsule (Brisdelle, discussed later in chapter [see subsection "Menopausal Vasomotor Symptoms"]) and as 10-mg, 20-mg, 30-mg, and 40-mg tablets. The product labeling for these tablets (Noven Therapeutics 2013) does not describe them as being bioequivalent to paroxetine hydrochloride tablets, and the FDA Orange Book (U.S. Food and Drug Administration 2023) does not list them as being bioequivalent. No studies have compared this formulation's efficacy against that of paroxetine hydrochloride, and case reports have indicated problems of decreased efficacy and poor tolerability for patients switched from paroxetine hydrochloride to paroxetine mesylate (Borgheini 2003).

Mechanism of Action

The means by which all antidepressants exert their therapeutic action are largely unknown, although some of the properties have been related to hypothetical mechanisms (Blier 2001; Blier *et al.* 1990). Sertraline, paroxetine, and all of the other SSRIs cause immediate elevations in extracellular serotonin concentrations in serotonergic synapses, resulting from the decreased serotonin clearance associated with 5-HTT inhibition (Wagstaff *et al.* 2002). SSRIs initially cause a paradoxical *decrease* in serotonin neurotransmission, likely due to activation of a negative feedback system mediated by increased serotonin binding to the 5-HT$_{1A}$ autoreceptor and subsequent diminution in serotonergic neural activity (Blier *et al.* 1990). After 2-3 weeks of treatment, the 5-HT$_{1A}$ autoreceptors are desensitized, and there is an associated increase in serotonergic neurotransmission (Blier 2001; Chaput *et al.* 1991). The delayed changes in 5-HT$_{1A}$ receptor sensitivity and serotonin neurotransmission seen after long-term use are temporally associated with clinical improvement, hinting at a possible mechanistic link. Not inconsistent with this are findings suggesting that SSRI treatment decreases production of serotonin$_{1B}$ messenger RNA, the message for a regulatory autoreceptor on dorsal raphe neurons that controls the amount of serotonin released with each impulse (Anthony *et al.* 2000). Again, the decrease in messenger RNA production coincides with the time frame for SSRI therapeutic effects.

Indications and Efficacy

Major Depressive Disorder

Sertraline

Sertraline's efficacy in the treatment of major depressive disorder (MDD) was established by a number of placebo-controlled trials for acute-phase therapy (Fabre *et al.* 1995; Olie *et al.* 1997; Reimherr *et al.* 1990). In a multicenter trial, 369 patients were randomly assigned to a fixed dosage of sertraline (50, 100, or 200 mg/day) or placebo for 6 weeks (Fabre *et al.* 1995). Patients at all dosages of sertraline showed approximately equivalent improvement, which was greater than that shown with placebo for most measures.

Sertraline was compared with amitriptyline and placebo in a multicenter trial of 448 patients (Reimherr *et al.* 1990). Sertraline was dosed flexibly up to 200 mg/day, and amitriptyline was administered at dosages as high as 150 mg/day. Both active treatments were superior to placebo, as indicated by Hamilton Rating Scale for Depression (Ham-D) and Clinical Global Impression (CGI) Scale scores; similarly, response rates (i.e., rates at which patients attained a 50% decrease in Ham-D score or a CGI score of 1 or 2) were higher with the active treatment compared with placebo.

In a multicenter study of 235 men and 400 women with either chronic MDD (enduring at least 2 years) or MDD superimposed on DSM-IV (American Psychiatric Association 1994) dysthymic disorder, participants were randomly assigned to 12 weeks of either sertraline or imipramine in a 2:1 ratio (Kornstein *et al.* 2000). Treatment was double blinded, and the study medication was titrated to a flexible maximum daily dosage of sertraline 200 mg or imipramine 300 mg. Response to both drugs was similar, but sertraline was better tolerated. The results revealed that many who benefited had not achieved response until after 8 weeks of treatment, underscoring the need for extended sertraline trials in patients with chronic depression (Keller *et al.* 1998a). Another interesting finding from this study is that men and women differed in their response to sertraline and imipramine (Kornstein *et al.* 2000). Remission and response outcomes were combined in an intent-to-treat analysis that showed that 57% of women, but only 46% of men, benefited from sertraline. Among men, response was somewhat better with imipramine than with sertraline (62% and 45%, respectively). Response was more rapid for men assigned to imipramine and for women assigned to sertraline. Among women, those who were premenopausal were more likely to respond to sertraline, whereas postmenopausal women were equally likely to respond to either agent.

Several trials have shown roughly equivalent efficacy for sertraline and other SSRIs (Aguglia *et al.* 1993; Franchini *et al.* 1997; Newhouse *et al.* 2000; Stahl 2000). However, a Cochrane Database review and meta-analysis of all randomized controlled trials of sertraline against an active antidepressant comparator concluded that sertraline was superior to other agents for the treatment of MDD in terms of both efficacy and acceptability (Cipriani *et al.* 2010).

In the Establishing Moderators and Biosignatures of Antidepressant Response for Clinical Care (EMBARC) trial on biomarker development, sertraline was not significantly more effective than placebo in MDD (Webb *et al.* 2019). However, low ventral striatal activity on functional MRI at baseline appeared to predict separation of sertraline from placebo (Greenberg *et al.* 2020). In addition, decreased irritability with treatment was associated with significant separation in overall response between sertraline and placebo in those patients (Jha *et al.* 2020).

Sertraline has been shown to be effective for maintenance-phase treatment, both for patients with MDD (Doogan and Caillard 1992) and for individuals with chronic MDD (defined as a major depressive episode enduring at least 2 years or co-occurring with dysthymic disorder) (Keller *et al.* 1998b). The Doogan and Caillard (1992) study followed 300 patients throughout 44 weeks of double-blind, placebo-controlled maintenance therapy and found that 13% of sertraline-treated patients, compared with 46% of placebo-treated patients, experienced relapse.

Keller *et al.* (1998b) examined the utility of sertraline in preventing illness recurrence among patients with chronic MDD who responded to acute antidepressant therapy (n = 161). Participants were randomly assigned to receive 52 weeks of maintenance treatment with either placebo or sertraline. More than 60% of the sample was female and had a current episode duration that exceeded 8 years. Sertraline significantly outperformed placebo on all outcome measures; 6% of sertraline-treated patients and 23% of placebo-treated patients experienced depressive episode recurrence, and clinically significant depressive symptom reemergence was observed for 26% of patients receiving sertraline versus 50% of patients receiving placebo.

Sertraline can be used to treat MDD in special populations. In addition to the trials just described, several studies found sertraline to be at least as effective as TCAs in treating younger adults (Cohn *et al.* 1990; Lydiard *et al.* 1997; Moller *et al.* 1998) and elderly patients (Bondareff *et al.* 2000; Finkel *et al.* 1999; Forlenza *et al.* 2001) with MDD. A recent small study reported that vortioxetine and sertraline were similarly effective in treating depression among elderly persons (Borhannejad *et al.* 2020). Although some studies reported that sertraline was used successfully in the treatment of children and adolescents with MDD and dysthymic disorder (Ambrosini *et al.* 1999; Nixon *et al.* 2001), a meta-analysis determined that only fluoxetine was significantly more effective than placebo for MDD in this population (Cipriani *et al.* 2016), and sertraline is not FDA approved for MDD in this age group. Sertraline has been shown to be as beneficial as nortriptyline in women with postpartum MDD (Wisner *et al.* 2006). Sertraline was significantly more effective than placebo in reducing depressive symptoms of postpartum depression (Hantsoo *et al.* 2014), particularly in women whose symptoms began within 4 weeks of giving birth. However, in another recent trial, specialized cognitive-behavioral therapy (CBT) was significantly more effective than sertraline in women with postpartum depression (Milgrom *et al.* 2015). Sertraline may confer a prophylactic advantage in women at high risk for developing postpartum episodes of MDD (Wisner *et al.* 2004), and sertraline is one of three antidepressants judged to be evidence-based choices for MDD in women who are breastfeeding (Lanza di Scalea and Wisner 2009).

Sertraline has been used to treat mood symptoms associated with a number of neurological conditions, including depression associated with Parkinson's disease (Antonini *et al.* 2006; Hauser and Zesiewicz 1997; Meara and Hobson 1998) and depression-linked fatigue in multiple sclerosis (Mohr *et al.* 2003). Sertraline also has been used to improve pathological crying and pseudobulbar-type affects (Benedek and Peterson 1995; Mukand *et al.* 1996; Okun *et al.* 2001; Peterson *et al.* 1996). In the "psychological subgroup" of a cohort of patients with Alzheimer's disease, mirtazapine, but not sertraline, separated from placebo (Zuidersma *et al.* 2019).

Sertraline is one of the few antidepressants shown to be safe for the treatment of depression in patients with cardiovascular disease. In a well-publicized study by the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) Group, there were no significant treatment-emergent effects of sertraline on cardiac measures (including change from baseline left ventricular ejection fraction, runs of ventricular premature complexes, or prolonged QTc intervals) (Glassman *et al.* 2002). For the entire sample, sertraline was superior to placebo in improving rates of response when defined by CGI ratings, but not when defined by Ham-D scores (Glassman *et al.* 2002). Although sertraline's safety was again demonstrated in a study of 469 SADHART patients with chronic heart failure, in this sample there was no evidence of antidepressant superiority of sertraline over placebo (O'Connor *et al.* 2010). Compared with chronic heart failure patients with nonremitting depression, those who achieved remission from depression had fewer cardiovascular events at pretreatment baseline and went on to have better cardiovascular outcomes over a 5-year period (Jiang *et al.* 2011).

Sertraline has been studied in patients with cancer and depression. A 12-week open-label, flexible-dose trial of sertraline in patients undergoing chemotherapy demonstrated positive effects on depressed mood (Torta *et al.* 2008). However, in a controlled trial of almost 200 patients with advanced disease who did not have MDD, sertraline had no mood benefit over placebo (Stockler *et al.* 2007).

Paroxetine

The efficacy of paroxetine in MDD has been established in several randomized placebo-controlled studies as well as in studies comparing the effects of paroxetine with

those of other antidepressants, including TCAs, serotonin-norepinephrine reuptake inhibitors, and other SSRIs. The earliest placebo-controlled studies used paroxetine dosages of 10-50 mg/day and were about 6 weeks in duration. A more recent meta-analysis of all published and unpublished industry-sponsored trials that included Ham-D change scores showed superiority of paroxetine over placebo, with a modest effect size of 0.32 (Sugarman *et al.* 2014). Barbui *et al.* (2008) undertook a systematic review of paroxetine, evaluating both published and unpublished data according to one specific hard measure--treatment discontinuation--by looking at the number of patients who left a study early for any reason. The authors found that when this measure was used as a primary outcome, paroxetine was not effective; when rate of response (defined as a 50% reduction or greater in Ham-D score) was used, paroxetine was superior to placebo (Barbui *et al.* 2008).

A meta-analysis by Montgomery (2001) compared the efficacy and tolerability of paroxetine with that of TCAs, including amitriptyline, imipramine, clomipramine, doxepin, and nortriptyline, as well as the tetracyclic antidepressants mianserin and maprotiline. The data demonstrated no overall significant difference in antidepressant response rates between paroxetine and TCAs or tetracyclics. However, paroxetine was better tolerated, had lower rates of discontinuation attributed to adverse events, and had a greater effect on concomitant anxiety.

Many studies have found paroxetine and fluoxetine to be equally effective in the treatment of MDD and associated anxiety (Chouinard *et al.* 1999; De Wilde *et al.* 1993; Fava *et al.* 1998, 2000; Tignol 1993). Equivalent efficacy was demonstrated in comparisons of paroxetine against either sertraline or escitalopram; however, these studies tended to also show a greater dropout rate in paroxetine groups, likely owing to adverse medication effects (Aberg-Wistedt *et al.* 2000; Baldwin *et al.* 2006; Zanardi *et al.* 1996). Some studies have suggested efficacy differences among the SSRIs, with a Cochrane Review concluding that citalopram may be superior to paroxetine in the acute phase of treatment (6-12 weeks) (Purgato *et al.* 2014).

Paroxetine has also been compared with a variety of other agents in the treatment of depression. Nefazodone and paroxetine were demonstrated to possess similar efficacy and tolerability (Baldwin *et al.* 1996), and mirtazapine and paroxetine were equivalent in terms of efficacy and tolerability (Benkert *et al.* 2000). However, in a Cochrane Review, Purgato *et al.* (2014) concluded that mirtazapine may be superior to paroxetine, whereas paroxetine may be superior to the norepinephrine reuptake inhibitor reboxetine in terms of early response to treatment (1-4 weeks). In a meta-analysis of worldwide data from studies of venlafaxine, the serotonin-norepinephrine reuptake inhibitor venlafaxine showed a slight statistically significant advantage in efficacy over SSRIs as a class, although no such advantage was demonstrated for venlafaxine over paroxetine (Nemeroff *et al.* 2003).

Studies have demonstrated the effectiveness of paroxetine in maintaining remission over an extended period without adverse effects (Duboff 1993), particularly when compared with placebo (Montgomery and Dunbar 1993). The paroxetine dosages used in the long-term studies were typically the same ones used in the acute studies (20-40 mg/day). Thus, for maintenance therapy for depression, the recommended dosage of paroxetine is the one that was effective during acute therapy.

Numerous studies have established the efficacy of paroxetine in treating depression in elderly patients (Geretsegger *et al.* 1995; Guillibert *et al.* 1989; Hutchinson *et al.* 1992; Rapaport *et al.* 2009) and for maintenance treatment in this population (Bump *et al.* 2001; Reynolds *et al.* 2006). A recent network meta-analysis determined that there is clear evidence for the effectiveness of paroxetine in depression in older adults, but paroxetine may have a greater risk of dizziness compared with placebo (Thorlund *et al.* 2015). One issue of concern in treating elderly individuals with paroxetine is the potential risk of anticholinergic side effects, leading to delirium. However, in a study comparing the effects of fluoxetine and paroxetine in depressed elderly patients without dementia, both medications produced marked improvement in cognitive functioning and mood symptoms and were well tolerated (Cassano *et al.* 2002). A meta-analysis concluded that paroxetine was not significantly associated with risk of falls in older adults (Ruxton *et al.* 2015).

Published data on paroxetine have shown limited efficacy in children and adolescents with MDD (Emslie *et al.* 2006; Keller *et al.* 2001). Paroxetine is not approved for use in pediatric patients (GlaxoSmithKline 2019). In a reanalysis of the Keller *et al.* (2001) study, Le Noury *et al.* (2015) found that the benefits of paroxetine were lower and the risks greater than had been reported in the initial publication. In particular, paroxetine did not show greater efficacy than placebo and was associated with increased risks, including suicidal ideation and behavior (Le Noury *et al.* 2015). Differences in pharmacokinetics between children and adults may explain the observed age-related discrepancies in efficacy and suicide risk. In children, an increase in dosage from 10 to 20 mg results in a sixfold increase in serum paroxetine levels (Findling *et al.* 1999). This dramatic increase in pediatric serum levels could conceivably trigger activation, akathisia, or disinhibition, potentially explaining the emergence of suicidal thinking or behavior (Brent 2004), and the effect would be even greater in children who are poor CYP2D6 metabolizers (roughly 10% of the white population) (Riddle 2004). In addition, paroxetine has a relatively short half-life (11 hours, vs. 5 days with fluoxetine), and limited treatment adherence--not uncommon in children and teens--could lead to SSRI discontinuation syndrome and dysphoria (Brent 2004).

Paroxetine is reported to be efficacious in the treatment of depression comorbid with several medical disorders, including rheumatoid arthritis, irritable bowel syndrome, cardiovascular disease, and Parkinson's disease (Bird and Broggini 2000; Masand *et al.* 2001; Richard *et al.* 2012; Roose *et al.* 1998). Along with escitalopram, paroxetine was one of the most recommended medications for poststroke depression in a recent review based on randomized controlled trials and meta-analyses (Starkstein and Hayhow 2019). However, another meta-analysis of four poststroke depression studies showed no advantage for paroxetine over placebo (Li *et al.* 2020a). Paroxetine has also been demonstrated to be efficacious in the prevention of interferon-a-induced depression in patients with malignant melanoma (Musselman *et al.* 2001).

Social Anxiety Disorder

Sertraline

Sertraline, paroxetine, controlled-release fluvoxamine, and extended-release venlafaxine are the only medications with FDA approval for the treatment of social anxiety disorder. Several studies have established the efficacy of sertraline in the treatment of social anxiety disorder. In one of the earliest studies (Katzelnick *et al.* 1995), sertraline treatment (at flexible dosages of 50-100 mg/day) produced a statistically significant improvement compared with placebo, as measured by Liebowitz Social Anxiety Scale scores. A large double-blind, placebo-controlled study followed more than 200 Canadian outpatients with generalized social anxiety disorder for 20 weeks, measuring response via CGI-Improvement (CGI-I) scores and mean reductions on the social phobia subscale of the Marks Fear Questionnaire and the Brief Social Phobia Scale (Van Ameringen *et al.* 2001). Fifty-three percent of patients treated with sertraline, compared with only 29% of patients receiving placebo, were either much or very much improved by the study's end, as measured by CGI-I scores. When patients who responded to sertraline were randomly assigned to continue sertraline or switch to placebo for an additional 24 weeks, the RR of relapse for those randomly assigned to placebo was greater than 10 (Walker *et al.* 2000).

Liebowitz *et al.* (2003) demonstrated that sertraline produced a significant reduction in Liebowitz Social Anxiety Scale scores and resulted in a greater proportion of responders after 12 weeks of treatment (at dosages up to 200 mg/day) compared with placebo. In a placebo-controlled study that compared sertraline, exposure therapy, and combined treatment and involved more than 380 Norwegian patients with generalized social anxiety disorder, sertraline alone or in combination with exposure therapy yielded statistically significant improvements in CGI social phobia scores, whereas exposure therapy alone did not (Blomhoff *et al.* 2001). Although sertraline is not FDA approved in the pediatric population, it has been well tolerated and has shown efficacy in childhood social anxiety disorder (Compton *et al.* 2001).

Paroxetine

Paroxetine's efficacy in the treatment of social anxiety disorder was first suggested by results from open clinical trials (Mancini and Van Ameringen 1996; Stein *et al.* 1996) and was later confirmed by findings from double-blind, placebo-controlled studies (Baldwin *et al.* 1999; Stein *et al.* 1998). Recent meta-analyses have also confirmed that paroxetine is effective and well tolerated for social anxiety disorder and indicate that there is more evidence for the efficacy of paroxetine than for any other agent in this class (Li *et al.* 2020b; Williams *et al.* 2020). However, a randomized controlled trial reported that cognitive therapy was more effective than either paroxetine alone or the combination of paroxetine and cognitive therapy (Nordahl *et al.* 2016).

In children and adolescents (ages 8-17 years) with social anxiety disorder, paroxetine was superior to placebo (Wagner *et al.* 2004). It is important to note that a total of five patients in the paroxetine group (*n* = 163) exhibited suicidal threats or gestures, compared with none in the placebo group (*n* = 156).

It appears that the optimal daily dosage of paroxetine for the treatment of social anxiety disorder is 20-40 mg/day, with no additional benefit seen for 60 mg/day (Lydiard and Bobes 2000). In patients who respond to paroxetine, it is also advisable to continue treatment to prevent relapse (Stein *et al.* 2002).

Panic Disorder

Sertraline

Sertraline's efficacy in the treatment of panic disorder has been demonstrated in several studies. In a 12-week randomized, placebo-controlled, flexible-dose multicenter trial in outpatients with panic disorder (with and without agoraphobia) but without

depression (Pohl *et al.* 1998), sertraline was superior to placebo on a number of efficacy measures. Patients meeting diagnostic criteria for panic disorder (*n* = 168) without depression were randomly assigned to receive sertraline or placebo after a 2-week single-blind lead in. The mean +- SD sertraline dosage at endpoint was 126 +- 62 mg/day, and the reduction in panic attack frequency was significantly greater for the sertraline group than the placebo group (77% vs. 51%), with significantly fewer panic symptom episodes occurring in that group. Similar results supporting sertraline's efficacy for panic disorder were reported by Pollack *et al.* (1998), who randomly assigned 178 patients to sertraline or placebo.

A fixed-dosage study of sertraline (50, 100, or 200 mg/day) or placebo for 12 weeks (Londborg *et al.* 1998) demonstrated sertraline's superiority over placebo in numerous trial outcomes, including the number of panic attacks and limited-symptom attacks, severity of anticipatory anxiety, dimensional anxiety measures, and global measures of improvement. Pooled sertraline data indicated a 65% reduction in the number of panic attacks, compared with a 39% decrease in the placebo group. Effect sizes, reflecting the magnitude of difference between the two treatments, for the three different sertraline dosages tested were 0.58 (50 mg/day), 0.41 (100 mg/day), and 0.60 (200 mg/day), but response rates did not differ significantly among dosage groups. In the panic studies described above (Londborg *et al.* 1998; Pohl *et al.* 1998; Pollack *et al.* (1998), the authors reported a low incidence of attrition secondary to sertraline adverse events, concluding that sertraline is a safe and effective treatment for patients with panic disorder. Sertraline's beneficial effects in panic disorder may be further enhanced when the drug is used in combination with self-administered CBT (Koszycki *et al.* 2011).

Paroxetine

Paroxetine was the first SSRI to be granted FDA approval for the treatment of panic disorder. Paroxetine and clomipramine have been shown to be equally efficacious in the treatment of panic attacks, and a faster onset of action was noted with paroxetine (Lecrubier *et al.* 1997a). Paroxetine's long-term efficacy and tolerability have also been demonstrated in patients with panic disorder (Lecrubier *et al.* 1997b; Nardi *et al.* 2012). The combination of CBT and paroxetine is more effective in the treatment of panic disorder than CBT alone (Bakker *et al.* 1999; Oehrberg *et al.* 1995).

In general, patients with panic disorder should initially be treated with a low dosage of paroxetine (e.g., 10 mg/day), with gradual increases in dosage as clinically indicated. The data that led to FDA approval suggested that 40 mg/day was the minimum effective dosage for this condition;

however, clinical experience has shown that lower dosages may be sufficient for some patients and higher dosages may be required for other patients (Ballenger *et al.* 1998). The standard duration of treatment ranges from 6 to 12 months; however, rates of relapse for panic disorder appear to be greater than those for MDD, suggesting that panic disorder may require an indefinite course of treatment (Hirschfeld 1996).

Obsessive-Compulsive Disorder

Sertraline

Currently, the SSRIs fluvoxamine, fluoxetine, sertraline, and paroxetine are FDA approved for the treatment of OCD in adults. Several multicenter trials reported greater

benefit for sertraline versus placebo in the acute-and maintenance-phase treatment of OCD. One study did not show superiority of sertraline over placebo, perhaps because of the limited sample size (*n* = 19) or the treatment-resistant characteristics of the cohort (Jenike *et al.* 1990). Larger studies with diverse cohorts had differing results. By week 3 in a 12-week flexible-dose study in 167 patients (Kronig *et al.* 1999), sertraline (mean dosage 165 mg/day) had separated from placebo. At study endpoint, 41% of patients receiving sertraline (vs. 23% of those receiving placebo) had achieved a CGI-I score of 1 or 2.

In a fixed-dose multisite trial, Greist *et al.* (1995a) also found superior results with three different daily dosages (50, 100, or 200 mg) of sertraline compared with placebo over 1 year of treatment. Patients with OCD (*n* = 325) were randomly assigned to receive 12 weeks of double-blind treatment after a 1-week washout period. Responders (40% of sertraline-treated patients and 26% of placebo-treated patients) were offered enrollment in an additional 40 weeks of continuation treatment. Over the 52 weeks of the study, sertraline-treated patients demonstrated significantly greater improvement than did participants given placebo.

Some evidence suggests that higher daily dosages of sertraline may be helpful for patients whose symptoms do not respond to standard dosages. In one study, 66 patients with OCD that was unresponsive to sertraline therapy (200 mg/day) after 16 weeks of treatment were randomly assigned to continue on the same dosage for an additional 12 weeks or to increase their dosage (250-400 mg/day) (Ninan *et al.* 2006). At the end of the trial, patients taking higher dosages had greater improvement in Yale-Brown Obsessive Compulsive Scale scores, although rates of response were similar for the two groups.

Other studies supporting the utility of sertraline in OCD have included head-to-head comparisons with other antidepressants (e.g., vs. fluoxetine [Bergeron *et al.* 2002]; vs. clomipramine [Bisserbe *et al.* 1997]; vs. desipramine [Hoehn-Saric *et al.* 2000]). In a comparison of lower-dosage sertraline with cognitive-behavioral group therapy, both treatments were shown to be efficacious, although patients with OCD treated with group therapy had greater reductions in symptoms (Sousa *et al.* 2006). Continuation of CBT versus sertraline initiation in children and adolescents with OCD who had not responded to an initial trial of CBT resulted in similar efficacy (Skarphedinsson *et al.* 2015).

Sertraline is approved for use in children for the treatment of OCD. March *et al.* (1998) conducted a 12-week double-blind, placebo-controlled, parallel-group multicenter trial in 187 pediatric participants (107 children ages 6-12 years and 80 adolescents ages 13-17 years). They found that participants treated with sertraline (mean endpoint dosage 167 mg/day) showed significantly greater improvement in Yale-Brown Obsessive Compulsive Scale, National Institute of Mental Health Global Obsessive-Compulsive Scale, and CGI-I scores compared with those receiving placebo. There were few dropouts due to adverse events, and the authors concluded that sertraline is a safe, well-tolerated treatment in this age group (March *et al.* 1998). A subsequent study in children and adolescents treated with sertraline (50-200 mg/day) over 12 months reported that many who responded to acute treatment could achieve full or partial remission status with longer-term treatment (Wagner *et al.* 2003).

Paroxetine

Although two meta-analyses assessing the efficacy and tolerability of the TCA clomipramine and SSRIs in OCD seemed to favor clomipramine in terms of overall effectiveness (Greist *et al.* 1995b; Piccinelli *et al.* 1995), the only placebo-controlled multicenter study to compare clomipramine directly against an SSRI (paroxetine) revealed equal efficacy, with greater tolerability for paroxetine (Zohar *et al.* 1996).

Paroxetine also has demonstrated efficacy in pediatric OCD. In a randomized, double-blind, placebo-controlled multicenter trial (Geller *et al.* 2004), paroxetine was an effective and generally well-tolerated treatment for OCD in children and adolescents. Patients with comorbid MDD were excluded from this study, and only one incident of treatment-emergent suicidal behavior or ideation was reported.

In adults, paroxetine dosages of 60 mg/day or greater are usually required for optimal efficacy in OCD. Although patients usually respond to treatment within 3-4 weeks, clinical improvement may not be discernible until 10-12 weeks; therefore, a standard trial of up to 12 weeks should be conducted before an alternative medication is considered (Rasmussen *et al.* 1993).

Posttraumatic Stress Disorder

Sertraline

Among the SSRIs, sertraline and paroxetine have received FDA approval for the treatment of PTSD. Sertraline's efficacy in the treatment of PTSD is supported by two large acute-phase, double-blind, placebo-controlled multicenter studies (Brady *et al.* 2000; Davidson *et al.* 2001b), a long-term treatment study (Londborg *et al.* 2001), and a relapse prevention trial (Davidson *et al.* 2001a).

In the first acute-phase trial (Davidson *et al.* 2001b), 208 civilian patients were randomly assigned to receive either sertraline or placebo for 12 weeks. Observed rates of symptom reduction with active treatment were about 50% for reexperiencing/intrusion, just under 50% for avoidance/numbing, and 40% for arousal. The probability of response, defined as a CGI score of 1 or 2 and a minimal 30% decrease in Clinician-Administered PTSD Scale-Part 2 score, was 0.65 for sertraline-treated patients and 0.38 for placebo-treated patients at the 12-week endpoint. Approximately 40% of each group had comorbid MDD, with mean baseline 21-item Ham-D scores of around 21. Of interest, there were no significant differences among groups in depression symptom severity. The second acute-phase study (Brady *et al.* 2000) yielded similarly positive results.

In a pediatric sample with PTSD, 10 weeks of treatment with sertraline 50-200 mg/day appeared generally safe but did not produce outcomes superior to those with placebo (Robb *et al.* 2010).

Whereas the overall acute-phase efficacy of sertraline for PTSD was significant for women in the large controlled studies reviewed earlier (Brady *et al.* 2000; Davidson *et al.* 2001b), sertraline failed to differentiate from placebo in men. Some research suggests that treatment efficacy may vary by gender and by type of traumas experienced. Other research has shown no significant gender differences in sertraline's efficacy in patients with combat-related PTSD (Friedman *et al.* 2007). Reasons for the sex differences in efficacy findings are not clear, although one possible explanation is that women are more likely than men to experience sexual or physical trauma and childhood abuse. It is possible that the nature of the trauma itself (age at exposure, chronicity, or contextual factors) may alter the biology of the disorder and its responsiveness to medication (Stein *et al.* 2006).

Findings from a U.S. Department of Veterans Affairs medical center study failed to demonstrate that sertraline was superior to placebo for patients with predominantly combat-related PTSD (Friedman *et al.* 2007), but a subsequent trial in Iranian combat veterans (*n* = 70) did show a more robust efficacy for sertraline compared with placebo (Panahi *et al.* 2011).

Sertraline's long-term benefit for PTSD was demonstrated in a prospective study in which patients with PTSD who had completed 12 weeks of double-blind, placebo-controlled, acute-phase treatment with sertraline (Brady *et al.* 2000) were enrolled in a 24-week open-label continuation phase (Londborg *et al.* 2001). It was observed that about 20%-25% of the total improvement in PTSD symptoms occurred during the continuation phase (weeks 12-36). The greatest improvement over time was among patients who were originally considered "nonresponders" in the acute phase, leading the authors to conclude that as many as one-third of patients with PTSD may require longer treatment to achieve a clinically significant response. Sertraline's efficacy in sustaining improvement and preventing PTSD relapse was also examined in a 28-week double-blind continuation study ($n = 96$) (Davidson *et al.* 2001a). Sertraline was superior to placebo on the three primary outcome measures: full syndrome relapse (5.3% vs. 26.1%), relapse or discontinuation due to clinical deterioration (15.8% vs. 45.7%), and acute exacerbation (15.8% vs. 52.2%). The RR of relapse after discontinuing sertraline was 6.35.

A systematic review and meta-analysis concluded that trauma-focused psychotherapies should be considered first-line treatments for PTSD, while sertraline and venlafaxine appeared superior to other medications and should potentially be considered second-line treatments (Lee *et al.* 2016). However, a more recent study found no difference in efficacy for sertraline, prolonged exposure, or their combination (Rauch *et al.* 2019).

Paroxetine

Compared with placebo, paroxetine (20-40 mg/day) has been shown to produce significant improvements in the three symptom cluster groups of reexperiencing, avoiding/numbing, and hyperarousal and to reduce disability and depression (Marshall *et al.* 1998, 2001). Patients with PTSD and comorbid MDD respond just as favorably as do individuals without depression. Similar findings have been reported by other groups (Tucker *et al.* 2001, 2004), and paroxetine has also shown efficacy in combination with prolonged exposure therapy (Schneier *et al.* 2012) and in long-term treatment (Kim *et al.* 2008; Vermetten *et al.* 2003). A recent study found that paroxetine was less effective than prolonged exposure in achieving symptom remission, and the combination of paroxetine and prolonged exposure was not superior to prolonged exposure alone (Popiel *et al.* 2015).

Generalized Anxiety Disorder

Extended-release venlafaxine, escitalopram, duloxetine, and paroxetine have all been approved by the FDA for treatment of generalized anxiety disorder, whereas sertraline has not. The first published study supporting the use of paroxetine in generalized anxiety disorder compared it with both imipramine and 2'-chlordesmethyldiazepam, a benzodiazepine (Rocca *et al.* 1997). Not surprisingly, patients receiving the benzodiazepine showed the earliest improvement in symptoms; however, both paroxetine

and imipramine produced significant reductions in Hamilton Anxiety Scale total score, exceeding the reductions produced by the benzodiazepine by week 4 of the 8-week trial. Subsequent studies further confirmed the efficacy of paroxetine in the treatment of generalized anxiety disorder (Bielski *et al.* 2005; Pollack *et al.* 2001; Rickels *et al.* 2003).

Long-term treatment of generalized anxiety disorder with paroxetine may be necessary (Stocchi *et al.* 2003). Clinical experience and investigative research indicate that the usual effective paroxetine dosage for treating generalized anxiety disorder is 20 mg/day (GlaxoSmithKline 2019).

Sertraline has also shown some benefit in the treatment of generalized anxiety disorder. Two randomized generalized anxiety disorder trials showed that sertraline had superiority over placebo (Allgulander *et al.* 2004; Brawman-Mintzer *et al.* 2006), and another trial demonstrated that sertraline had efficacy similar to that of paroxetine (Ball *et al.* 2005). In a placebo-controlled trial (Rynn *et al.* 2001), sertraline was both effective and safe in children with generalized anxiety disorder.

Premenstrual Dysphoric Disorder

Sertraline

Fluoxetine, sertraline, and paroxetine are FDA approved for the treatment of premenstrual dysphoric disorder. The somatic features of premenstrual dysphoric disorder--bloating, weight gain, breast tenderness, poor concentration, and disturbed sleep and appetite--manifest in the luteal phase of ovulation and disappear with the onset of menstruation. These symptoms are cyclical, predictably appearing prior to each menses (Dimmock *et al.* 2000). The psychological symptoms of premenstrual dysphoric disorder are more severe and prominent and include irritability, dysphoria, tension, and mood lability. In one of the first multicenter trials to test the efficacy of an antidepressant agent for premenstrual dysphoric disorder, sertraline was compared with placebo (Yonkers *et al.* 1997). Either placebo or sertraline (at a flexible daily dosage of 50-150 mg) was given to each participant ($N =$ 243 women). After three menstrual cycles of treatment, total daily rating scores had decreased by 32% and 11% in the sertraline-and placebo-treated groups, respectively. Both emotional and physical symptom clusters improved by 32% with sertraline treatment, a reduction nearly threefold higher than that seen with placebo. At the endpoint, CGI-I scores of 1 or 2 were achieved by 62% and 34% of those assigned to sertraline and placebo, respectively.

In a second multicenter trial, it was shown that sertraline treatment could be commenced halfway through the menstrual cycle (i.e., at ovulation) and still be more effective than placebo (Halbreich *et al.* 2002). In this three-cycle, flexible-dosage study, 281 women were randomly assigned to receive sertraline 50-100 mg/day or placebo. The responder rates in this study, after three cycles of luteal-phase treatment, were 50% and 26% for sertraline and placebo, respectively. As with the daily treatment study, functional improvement paralleled symptomatic improvement. Only 8% of the women taking sertraline and 1% of the women receiving placebo discontinued the study because of side effects. The efficacy of this drug administration schedule for women with premenstrual dysphoric disorder has the potential to revolutionize treatment approaches, because many women with premenstrual dysphoric disorder prefer to avoid taking medication during nonsymptomatic periods.

A secondary analysis of data from three large federally sponsored trials (n = 447) indicated that women with premenstrual syndrome showed positive responses to sertraline, similar to outcomes observed for women with premenstrual dysphoric disorder (Freeman *et al.* 2011). Examination of symptom-based subtypes in that analysis revealed that predominantly psychological symptoms or mixed psychological and physical symptoms predicted better response to sertraline than did predominantly physical symptoms.

Paroxetine

Paroxetine has been shown to be significantly more effective than the tetracyclic maprotiline, a norepinephrine reuptake inhibitor, in reducing both psychological and somatic symptoms of premenstrual dysphoric disorder (Eriksson *et al.* 1995). Two small open trials reported positive findings with paroxetine treatment (Sundblad *et al.* 1997; Yonkers *et al.* 1996), and a double-blind, placebo-controlled study demonstrated that controlled-release paroxetine (25 mg/day) was both well tolerated and effective in the treatment of premenstrual dysphoric disorder (Cohen *et al.* 2004).

Premenstrual dysphoric disorder can be successfully managed with intermittent luteal-phase dosing, in which the medication is started 14 days before the estimated next menses and continued until the onset of menstruation (Steiner *et al.* 2005). It has been shown that paroxetine improves irritability within 14 hours of taking the first dose (Landen *et al.* 2009). Both luteal-and continuous-phase dosing of paroxetine (either the controlled-or immediate-release formulation) are superior to placebo in relieving the psychological symptoms of premenstrual dysphoric disorder, but not the somatic symptoms (food craving, breast tenderness) (Steiner *et al.* 2005, 2008). Somatic symptoms may be better addressed with continuous treatment (Landen *et al.* 2007; Wu *et al.* 2008); however, with intermittent dosing, patients experience fewer adverse effects (Steiner *et al.* 2008).

Menopausal Vasomotor Symptoms

In addition to its proven efficacy in premenstrual dysphoric disorder, paroxetine is efficacious in treating perimenopausal hot flashes (Simon *et al.* 2013; Soares *et al.* 2008; Stearns *et al.* 2003). In 2013, a new formulation--paroxetine mesylate 7.5-mg capsules, marketed as Brisdelle--became the first nonhormonal medication to receive FDA approval for this indication (Noven Therapeutics 2013). The mechanism of action may involve a paroxetine-induced increase in brain-derived neurotrophic factor (BDNF) plasma levels (Cubeddu *et al.* 2010). It should be noted that higher strengths of paroxetine mesylate have not been approved for treatment of menopausal vasomotor symptoms.

Earlier studies also showed paroxetine (20 mg/day) to be effective in the treatment of postmenopausal hot flashes in survivors of breast cancer who had experienced chemotherapy-induced ovarian failure (Stearns *et al.* 2000, 2005; Weitzner *et al.* 2002). However, it is important to consider the risks of paroxetine in women with estrogen receptor-positive breast cancer who are taking tamoxifen to decrease the risk of breast cancer relapse. Tamoxifen is a prodrug that requires CYP2D6 metabolism to create its more active metabolite, endoxifen; however, as a potent inhibitor of CYP2D6, paroxetine blocks the conversion of tamoxifen to endoxifen (Kelly *et al.* 2010). An increased risk of death from breast cancer has been observed for women taking tamoxifen and paroxetine (Kelly *et al.* 2010).

Sertraline has been proposed as an off-label treatment for women to alleviate hot flashes associated with menopause (Aedo *et al.* 2011; Gordon *et al.* 2006; Grady *et al.* 2007) and with tamoxifen treatment for breast cancer (Kimmick *et al.* 2006), as well as for men who have received androgen-deprivation therapy for advanced prostate cancer (Roth and Scher 1998). One study suggested that a positive response to sertraline for hot flashes is related to activity level, education, and menopausal status (Kerwin *et al.* 2007).

Sertraline was superior to placebo in a study that examined its potential for controlling hot flashes in women with or at high risk for breast cancer for whom hormone therapy was not recommended (Wu *et al.* 2009).

Side Effects and Toxicology

The popularity of SSRIs as a class in the treatment of psychiatric disorders is owed not to their superiority in efficacy over their predecessors but rather to their overall tolerability and safety. The most commonly reported side effects of sertraline in clinical trials are nausea, diarrhea or loose stool, tremor, dyspepsia, decreased appetite, hyperhidrosis, ejaculation failure, and decreased libido (Pfizer 2021). The most commonly cited adverse experiences in patients treated with paroxetine are nausea, headache, somnolence, dry mouth, asthenia, sweating, constipation, dizziness, and tremor (Boyer and Blumhardt 1992).

Sexual Dysfunction

All SSRIs and serotonin-norepinephrine reuptake inhibitors have been associated with male and female sexual dysfunction. In a comparison study of 200 individuals, paroxetine treatment was associated with higher rates of anorgasmia in women and ejaculation difficulty or impotence in men compared with fluoxetine, fluvoxamine, and sertraline (Montejo-Gonzalez *et al.* 1997). In a large cross-sectional observational study (Clayton *et al.* 2002), paroxetine was associated with the highest rates of sexual dysfunction among the antidepressants evaluated (mirtazapine, venlafaxine, sertraline, citalopram, fluoxetine, nefazodone, and bupropion). More recently, paroxetine was reported to cause significantly worse sexual side effects than placebo in healthy control subjects (Jacobsen *et al.* 2019). In contrast, vortioxetine did not demonstrate similarly severe side effects (Jacobsen *et al.* 2019).

Sexual side effects emerge in a dose-dependent fashion and do not appear to diminish with prolonged administration; however, the effect is reversible, with most patients returning to normal functioning within 1 month of discontinuing the medication (Tanrikut *et al.* 2010). Strategies to lessen the impact of psychotropic medications on sexual function include reducing the dosage, changing to a different antidepressant with less sexual side-effect liability, and adding an agent (e.g., sildenafil, yohimbine, buspirone, cyproheptadine, amantadine, methylphenidate, bupropion) to reverse the sexual side effects (Rosen *et al.* 1999). A Cochrane Database review noted that although limited evidence is available, some trials have suggested that the addition of sildenafil or bupropion can reduce antidepressant-induced erectile dysfunction in men (Rudkin *et al.* 2004).

The sexual side effects of paroxetine have led to its use in the treatment of premature ejaculation. Paroxetine produces a greater delay in time to ejaculation compared with fluoxetine, fluvoxamine, sertraline, duloxetine, and mirtazapine (Safarinejad 2006; Waldinger *et al.* 1998, 2003), and a recent meta-analysis concluded that paroxetine is superior to placebo, fluoxetine, and escitalopram in the treatment of premature ejaculation (Zhang *et al.* 2019). Several studies have also reported sertraline's benefit in treating premature ejaculation (Arafa and Shamloul 2006; Biri *et al.* 1998).

Hemostasis

Sertraline, paroxetine, and other SSRIs have been associated with modification of hemostasis, related to blockade of platelet serotonin reuptake. Blockade may lead to serotonin depletion in platelets, which can result in inhibition of serotonin-induced platelet aggregation. This risk may be greater in patients with a preexisting platelet disorder (Halperin and Reber 2007). For example, in one retrospective series of cases describing patients who had received a ventricular assist device, use of an SSRI was associated with an increased risk of bleeding (Auschra *et al.* 2022).

Suicidality

In 2004, the FDA released a statement regarding a possible increased risk of suicidal thinking and suicide attempts in children and adolescents age 18 or younger who are treated with antidepressants, including sertraline and paroxetine, for MDD (Newman 2004). The statement was based on data from three well-controlled unpublished studies, each showing no benefit for paroxetine over placebo in the treatment of pediatric depression. The data also revealed an increased rate of suicidal ideation and suicide attempts with paroxetine treatment versus placebo (3.4% vs. 1.2%). There are no specific data indicating increased rates of suicide in children treated with sertraline.

In late 2006, an FDA advisory committee extended the black box warning to cover young adults up to their mid-20s (Friedman and Leon 2007). The committee reported that 1) in patients ages 18-24 years, antidepressant use was associated with four cases of suicidal ideation per 1,000 patients treated; 2) there was no evidence of increased risk in adults older than 24 years; and 3) antidepressant treatment was unequivocally protective against suicidality in patients ages 65 years and older.

Clinicians should inform their patients about the possible risks and should monitor patients with depression closely when they prescribe sertraline, paroxetine, or any other antidepressant, particularly during the early phase of treatment. The FDA advisory committee has made it clear that the black box warning should not dissuade physicians from prescribing antidepressants to patients in need (Friedman and Leon 2007).

Hyponatremia

Sertraline, paroxetine, and other SSRIs have been associated with cases of hyponatremia as well as with the syndrome of inappropriate antidiuretic hormone (SIADH) secretion (see Bouman *et al.* 1997; Bradley *et al.* 1996; Catalano *et al.* 1996; Goldstein *et al.* 1996; Kessler and Samuels 1996). In a review of the literature, Bradley *et al.* (1996) noted that patients experiencing SIADH were older than age 70 years on average, suggesting that elderly individuals may be more vulnerable to age-related changes in water balance, which may make them more susceptible to developing SIADH with an SSRI.

Extrapyramidal Side Effects

Extrapyramidal side effects, including dyskinesias, dystonias, and akathisia, have been observed with the use of SSRIs, including sertraline and paroxetine, although they are infrequent (Altshuler and Szuba 1994; Lambert *et al.* 1998; Madhusoodanan and Brenner 1997; Opler 1994; Revet *et al.* 2020). Hamilton and Opler (1992) suggested that the underlying mechanism of SSRI-induced akathisia is serotonergic inhibition of the nigrostriatal dopamine pathway, which can be associated with parkinsonism (Leo *et al.* 1995; Pina Latorre *et al.* 2001). Madhusoodanan and Brenner (1997), in a case report of choreiform dyskinesia and extrapyramidal side effects associated with sertraline therapy, proposed that serotonin-driven antagonism of dopaminergic transmission in the nigrostriatal pathway, as well as in the ventral tegmental area, might be responsible.

Discontinuation Syndrome

With abrupt discontinuation or treatment interruption, patients may develop what has become known as SSRI discontinuation syndrome. Symptoms (e.g., dizziness, paresthesias, agitation, anxiety, nausea, and sweating) occur as early as the second day after a missed dose and may persist for several days. A comparison of SSRI postmarketing safety data reported that withdrawal-related events occurred more frequently in patients treated with paroxetine than in individuals treated with sertraline, fluvoxamine, or fluoxetine and these events had a mean duration of 10.2 days (Price *et al.* 1996); similar results were reported by other groups (Michelson *et al.* 2000; Montgomery *et al.* 2004; Rosenbaum *et al.* 1998). Studies examining the effect of shorter SSRI treatment interruptions (3-5 days)--similar to what a patient would experience if they missed just a few medication doses--found that whereas paroxetine-treated patients develop significant discontinuation-emergent effects, fluoxetine-treated patients do not, a disparity likely due to differences in the half-lives of these medications (Judge *et al.* 2002; Michelson *et al.* 2000). In a systematic 28-week study in patients with panic disorder (Rapaport *et al.* 2001), abrupt discontinuation of sertraline was primarily associated only with insomnia (15.7% of patients randomly assigned to placebo vs. 4.3% continuing on sertraline) and dizziness (16.4% of patients switched to placebo vs. 4.3% continuing on sertraline). There was no statistically significant increase in headache or general malaise in patients randomly assigned to switch to placebo.

Use During Pregnancy and Lactation

The safety of sertraline, paroxetine, and other SSRIs during pregnancy is discussed in Chapter 63 ("Psychopharmacology During Pregnancy and Lactation"). A large-scale study in Quebec reported that exposure to sertraline during the first trimester was associated with an increased risk of cardiac (atrial or ventricular) effects and craniosynostosis (Berard *et al.* 2015). A recent meta-analysis of cohort studies also found that sertraline was associated with septal defects, atrial septal defects, and respiratory system defects (Gao *et al.* 2018).

Paroxetine was the only SSRI to be allocated to FDA Pregnancy Category D ("There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks") (U.S. Food And Drug Administration (2021), although the FDA pregnancy letter categories were removed with adoption of the pregnancy and lactation labeling rule (PLLRL) in 2015 (U.S. Food And Drug Administration (2014). Spontaneous abortion has been linked both to depression and to antidepressant use; the risk may be even greater for women who are treated with paroxetine or venlafaxine (Nakhai-Pour *et al.* 2010). Compared with other SSRIs, however, paroxetine has lower transmission across the placenta, and cord blood concentrations do not correlate with maternal dosing (Hendrick *et al.* 2003b). Maternal CYP2D6 polymorphisms appear to affect the pharmacokinetics of paroxetine. Women characterized as extensive metabolizers show decreases in paroxetine plasma levels over the course of pregnancy, whereas women characterized as intermediate or poor metabolizers show increased paroxetine levels (Ververs *et al.* 2009). It is possible that this effect may translate to a greater risk of fetal teratogenicity for women who are poor or intermediate metabolizers (Ververs *et al.* 2009).

Teratogenicity is a major concern when prescribing medications to women of childbearing age. The results of an unpublished study by GlaxoSmithKline (Paxil) led the FDA to warn that paroxetine may increase the risk of major congenital malformations (Williams and Wooltorton 2005). Several organ systems, including the CNS and gastrointestinal genitourinary systems, were affected; the most common cardiovascular anomalies were ventricular septal defects. A meta-analysis, also completed by GlaxoSmithKline, found a prevalence OR of 1.46 for combined cardiac defects with exposure to paroxetine in the first trimester. Considering a background prevalence of cardiac defects in the unexposed population of 1%, this would represent a 50% increase for the paroxetine-exposed population (Wurst *et al.* 2010).

In a cohort study comparing rates of major congenital malformations in infants born to women treated with paroxetine, fluvoxamine, or sertraline during pregnancy, researchers found no significant differences among the medication groups compared with the control group (Kulin *et al.* 1998). In another study comparing birth outcomes after prenatal exposure to paroxetine, fluoxetine, or sertraline, rates of neonatal complications and congenital malformations in antidepressant-exposed infants were lower (1.4%) than rates in the general population, with no significant differences among medications (Hendrick *et al.* 2003a). Whereas one prospective controlled observational study reported no increased risk of cardiac defects with paroxetine exposure (Diav-Citrin *et al.* 2008), a case-control study of data from a population-based registry of birth defects in the Netherlands showed an increased risk of atrial septal defects with first-trimester paroxetine exposure (adjusted OR, 5.7; 95% CI, 1.4-23.7) (Bakker *et al.* 2010). A meta-analysis of 23 studies concluded that paroxetine exposure during the first trimester was associated with a significantly increased risk of major congenital malformations, particularly major cardiac malformations (Berard *et al.* 2016). Another meta-analysis also found that paroxetine was associated with major congenital anomalies and congenital heart defects (Gao *et al.* 2018). It is important to

note that studies of teratogenicity are frequently complicated by the effects of depression itself or of polypharmacy (e.g., concurrent use of benzodiazepines) (Yonkers *et al.* 2009). Nevertheless, on the basis of the risk of malformations, the American College of Obstetricians and Gynecologists has recommended that paroxetine be avoided, if possible, in pregnant women or women planning pregnancy (ACOG Committee on Practice Bulletins--Obstetrics 2008).

Clinical studies of paroxetine in the setting of pregnancy suggest that gestational exposure might have transient negative effects on the newborn infant, particularly if the mother is treated during the third trimester. Infants with third-trimester paroxetine exposure show significantly increased distress compared with infants not so exposed (Costei *et al.* 2002). Symptoms in neonates exposed to SSRIs in utero include tremor, hypertonicity, irritability, weak or absent cry, seizures, and poor feeding; these symptoms typically resolve within 2 weeks (Knoppert *et al.* 2006; Yonkers *et al.* 2009). Debate continues among neonatologists as to whether this neonatal distress represents a manifestation of serotonin excess or serotonin withdrawal (Laine *et al.* 2004; Stiskal 2005, 2006).

If a woman opts to continue antidepressant treatment during pregnancy, the clinician is advised to monitor for relapse, given that higher dosages are often needed, especially in the early third trimester, to achieve or maintain disease remission (Hostetter *et al.* 2000).

A major review of SSRIs in breastfeeding concluded that sertraline and paroxetine are the preferred agents (in regard to the infant's health) for nursing women who require antidepressant treatment (Orsolini and Bellantuono 2015).

Drug-Drug Interactions

Combinations of medications that enhance serotonergic activity may result in serotonin toxicity (serotonin syndrome), manifesting as agitation, myoclonus, hyperreflexia, diarrhea, diaphoresis, delirium, fever, and possibly death (Weiner *et al.* 1997). Concomitant use of MAOIs with any of the SSRIs is absolutely contraindicated, and a washout period of 14 days is recommended when switching from one agent to another (Gunasekara *et al.* 1998; Weiner *et al.* 1997). Evidence of serotonin toxicity has been documented in case reports describing coadministration of paroxetine with moclobemide (Hawley *et al.* 1996), nefazodone (John *et al.* 1997), dextromethorphan (Skop *et al.* 1994), imipramine (Weiner *et al.* 1997), trazodone (Reeves and Bullen 1995), or other agents. The combination of SSRIs and sumatriptan, a serotonin$_{1D}$ receptor agonist used in the treatment of migraine, was previously discouraged because of the theoretical risk of precipitation of serotonin toxicity; however, a series of six cases, two involving sertraline and one involving paroxetine, of concurrent sumatriptan and SSRI administration demonstrated no such adverse events (Leung and Ong 1995).

Sertraline

Sertraline has a number of potential drug-drug interactions. Because the drug is tightly bound to plasma proteins, caution should be taken when sertraline is used in combination with pharmaceuticals possessing similar characteristics (e.g., warfarin),

and prothrombin time should be monitored when sertraline and warfarin are used concurrently (Pfizer 2021).

The degree of sertraline's inhibition of the CYP system, most significantly CYP2D6, is relatively minor compared with that of other SSRIs such as fluoxetine and paroxetine (Preskorn *et al.* 2007), although mouse data have shown a mild pharmacokinetic drug-drug interaction between bupropion and sertraline that leads to a small elevation in bupropion metabolism (Molnari *et al.* 2012). Because TCAs are substrates of CYP2D6, drug levels and dosages must be closely monitored when TCAs are used in combination with sertraline.

Sertraline, in common with its fellow SSRIs citalopram and escitalopram, is also metabolized by the CYP2C19 isoenzyme, which is inhibited by proton pump inhibitors. In a study examining the effect of proton pump inhibitors on serum concentrations of SSRIs, coadministration of esomeprazole led to significant elevations (+ 38.5%; $P = 0.0014$) in sertraline blood levels but caused an almost twofold increase (+ 81.8%; $P < 0.001$) in escitalopram blood levels (Gjestad *et al.* 2015).

Paroxetine

Paroxetine is dependent primarily on the CYP2D6 hepatic enzyme for conversion into its inactive metabolites (Hiemke and Hartter 2000). Paroxetine is not only a substrate of this system but also an inhibitor; therefore, other drugs that are metabolized by CYP2D6 are potentially subject to decreased clearance and subsequent increased plasma concentrations (Sindrup *et al.* 1992b). Concern is greatest for potential drug-drug interactions when the medication in question has a low therapeutic index.

Medications that are CYP2D6 dependent include many antipsychotics, TCAs, class IC antiarrhythmics, b-adrenergic agents, trazodone, and dextromethorphan (Nemeroff *et al.* 1996). Most reports of interactions between these medications and paroxetine are published as case reports (Lane 1996). As discussed earlier (see section "Menopausal Vasomotor Symptoms"), the breast cancer medication tamoxifen is converted to its active metabolite by CYP2D6, and there is evidence that paroxetine decreases the efficacy of tamoxifen and increases mortality in women with breast cancer who are taking tamoxifen (Kelly *et al.* 2010).

Paroxetine does not appear to potentiate the sedative effects of haloperidol (Cooper *et al.* 1989); however, dystonia has been reported with the combination (Budman *et al.* 1995). In one prospective study, clozapine serum levels increased by an average of 40% when clozapine was coadministered with SSRIs, including paroxetine at a mean dosage of 31.2 mg/day (Centorrino *et al.* 1996). In another study that used a lower dosage of paroxetine (20 mg/day), no significant increase in clozapine concentrations was noted (Wetzel *et al.* 1998). There is insufficient evidence to draw conclusions about the clinical significance of interactions between paroxetine and other second-generation antipsychotics (Spina and de Leon 2014). Case reports have described possible exaggeration of extrapyramidal side effects when paroxetine was coadministered with perphenazine (Ozdemir *et al.* 1997), molindone (Malek-Ahmadi and Allen 1995), or pimozide (Horrigan and Barnhill 1994).

Paroxetine was found to increase total exposure (i.e., area under the curve of plasma concentrations) to the b-adrenergic receptor antagonist nebivolol by a factor of 6.1 (Briciu *et al.* 2014). Paroxetine also increased plasma concentrations of the b-adrenergic

receptor antagonist timolol (administered as eye drops) to a level that could cause systemic adverse events in at-risk patients (Maenpaa *et al.* 2014).

Paroxetine is highly protein bound and has the potential to increase free drug levels of other medications that are bound to plasma proteins, such as warfarin, lithium, and digoxin, although this effect is rarely clinically meaningful (Bannister *et al.* 1989; Haenen *et al.* 1995; Preskorn 1993).

In prospective studies involving valproate, carbamazepine, or phenytoin, coadministration with paroxetine did not cause significant changes in plasma levels of these drugs (Andersen *et al.* 1991; Kaye *et al.* 1989). By contrast, both phenytoin and carbamazepine have been shown to decrease plasma paroxetine concentrations (Hiemke and Hartter 2000; Kaye *et al.* 1989). Valproate may increase plasma paroxetine concentrations (Andersen *et al.* 1991). Cimetidine, which is a potent inhibitor of the CYP2D6 isoenzyme, has been shown to result in a 50% elevation of paroxetine concentrations (Bannister *et al.* 1989). The clinical significance of these variations in paroxetine concentrations is minor because of its wide interindividual pharmacokinetic variability, high therapeutic index, and lack of a concentration-efficacy relationship (Gunasekara *et al.* 1998).

Paroxetine does not potentiate the psychomotor effects of amobarbital, oxazepam, diazepam, or alcohol (Bannister *et al.* 1989; Cooper *et al.* 1989).

Conclusion

Controlled clinical trials support sertraline and paroxetine's efficacy in the treatment of a variety of psychiatric conditions, including depressive and anxiety disorders. The safety profiles of sertraline and paroxetine are superior to those of older antidepressant agents, thus increasing the potential target population of patients for whom treatment can be beneficial.

CHAPTER 14

Citalopram and Escitalopram

Richard C. Shelton, M.D.

Citalopram (Celexa) and its pharmacologically active enantiomer, escitalopram (Lexapro), are among the most selective serotonin reuptake inhibitors available. Both drugs are widely prescribed and have been shown in large-scale controlled trials to be effective in the treatment of depression; escitalopram has also been shown to be effective in the treatment of anxiety disorders. Generic formulations of both drugs are now available. Both drugs are well tolerated by patients and show a low potential for pharmacokinetic drug-drug interactions, although higher-dosage citalopram treatment is associated with a clinically significant QT prolongation. Citalopram and escitalopram have similar effectiveness in the treatment of depression, although some studies suggest a modest superiority of escitalopram over citalopram on some measures of efficacy, including a possibly faster onset of therapeutic effect for escitalopram. Antagonism of the effects of escitalopram by *(R)*-citalopram has been invoked to explain the purported therapeutic differences between the two drugs. In addition, the affinity of citalopram for histamine receptors appears to reside in the *(R)*-enantiomer, suggesting that escitalopram has a decreased potential for antihistaminergic side effects. Finally, in terms of cardiac safety, citalopram has a greater potential to prolong the electrocardiographic QT interval and produce potentially serious arrhythmias.

History and Discovery

The pharmacology of citalopram was first described in 1977 (Christensen *et al.* 1977; Hyttel 1977). Citalopram was shown to be a very potent inhibitor of serotonin reuptake in both in vitro and in vivo models, with an inhibition constant (K_i) of approximately 1.5 nM (Hyttel 1977, 1978). It was subsequently discovered that all of the inhibitory activity of citalopram on serotonin reuptake resides in the *(S)*-(+)-enantiomer (escitalopram), with a K_i of approximately 1 nM (Hyttel *et al.* 1992; Owens *et al.* 2001; Sanchez *et al.* 2014). Originally introduced in Denmark in 1989, citalopram was approved by the FDA for the treatment of depression in July 1998. Citalopram is licensed in the United Kingdom and Europe for both depression and panic disorder; however, it is not FDA approved for the latter indication. Escitalopram received FDA approval for the treatment of major depressive disorder (MDD) in August 2002 and for the treatment of generalized anxiety disorder in December 2003. In addition, escitalopram received FDA approval in March 2009 for the treatment of MDD in adolescents ages 12-17 years.

Structure-Activity Relations

Citalopram has a single chiral center (Figure 14-1). A chiral center is an atom surrounded by an asymmetrical arrangement of atoms such that the three-dimensional configuration is not superimposable on its mirror image. At this chiral center, there are two possible stereoisomers. Often, drugs are produced as a mixture of both stereoisomers, referred to as the *racemate*. However, in some instances, different stereoisomers may have varying pharmacodynamics, pharmacokinetics, or toxicity, such that one form may be superior (Agranat *et al.* 2002). Citalopram was originally developed and marketed as the racemate, but subsequently the isolated stereoisomer of citalopram, escitalopram (Figure 14-2), was developed for the treatment of depression and other psychiatric disorders. Preclinical studies indicate that inhibition of serotonin transporter activity resides predominantly in the *(S)*-enantiomer (Hyttel *et al.* 1992), with escitalopram being over 30 times more potent than *(R)*-citalopram at inhibiting serotonin transport (K_i = 1.1 vs. 36 nM) (Owens *et al.* 2001).

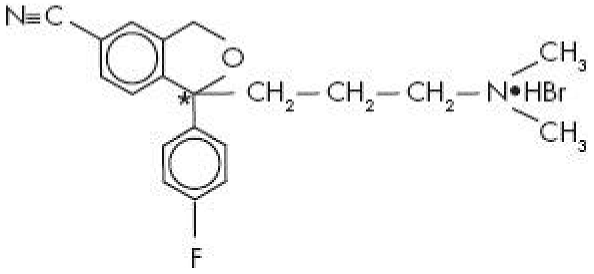

FIGURE 14-1. Chemical structure of citalopram hydrobromide.

*Indicates chiral center.

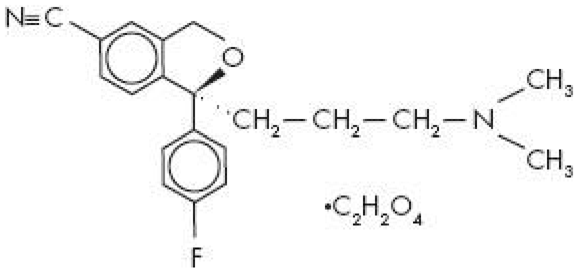

FIGURE 14-2. Chemical structure of escitalopram oxalate.

A possible explanation for the postulated modest superiority of escitalopram over citalopram on some measures of antidepressant efficacy is provided by evidence showing that the *(R)*-enantiomer of citalopram may interfere with the activity of the *(S)*-enantiomer, as demonstrated in several behavioral and physiological assays (for a review, see Sanchez 2006). In rat brain microdialysis studies, the administration of escitalopram with escalating levels of *(R)*-citalopram reduced serotonin reuptake blockade in a dose-dependent manner (Mork *et al.* 2003). Notably, *(R)*-citalopram and escitalopram in racemic citalopram have different clearance rates, resulting in an *(R)*-citalopram/escitalopram ratio of 2:1 (Brosen and Naranjo 2001). This antagonism has been hypothesized to result from a kinetic interaction at the serotonin transporter (Storustovu *et al.* 2004). Specifically, escitalopram is an allosteric modulator of the serotonin transporter; *(R)*-citalopram binds allosterically to the transporter, resulting in a conformation change that reduces the binding time of escitalopram (Sanchez 2006). Although there are effects in preclinical models, differences clinically are modest.

Pharmacological Profile

Citalopram

Of the selective serotonin reuptake inhibitors (SSRIs) approved to date, citalopram is one of the most selective, with a 524-fold lower potency for inhibiting the human norepinephrine transporter and a greater than 10,000-fold lower potency for inhibiting the human dopamine transporter (Owens *et al.* 2001). In addition, citalopram has low affinity for a wide variety of neurotransmitter receptors (for a review, see Hyttel *et al.* 1995). Citalopram has been reported to have submicromolar affinity for the histamine$_1$ receptor (K_i = 283 nM) (Hyttel 1994; Richelson and Nelson 1984), but this appears to be true only for the *(R)*-enantiomer (Owens *et al.* 2001). Citalopram does not show significant inhibition of monoamine oxidase (Hyttel 1977). Behavioral studies in rats and mice have shown citalopram to be a potent and selective inhibitor of serotonin reuptake (Christensen *et al.* 1977; Hyttel 1994). In contrast, citalopram has no in vivo effects on dopamine or norepinephrine reuptake (Hyttel 1994). Citalopram is active in various behavioral models related to antidepressant activity (Martin *et al.* 1990; Sanchez and Meier 1997) and anxiolytic activity (Inoue 1993; Sanchez 1995).

Escitalopram

Escitalopram is also a highly potent inhibitor of serotonin reuptake, with a K_i for binding to the human serotonin transporter of 1.1 nM, compared with 1.9 nM for citalopram and 36 nM for *(R)*-citalopram (Owens *et al.* 2001). Escitalopram is the most selective SSRI approved for clinical use, with a 2,600-fold lower potency for inhibiting the human norepinephrine transporter and a greater than 45,000-fold lower potency for inhibiting the human dopamine transporter. Escitalopram has no appreciable binding affinity for a large number of other neurotransmitter receptors (Owens *et al.* 2001; Sanchez *et al.* 2003). Escitalopram shows potent activity in various in vivo paradigms, including a model of serotonin reuptake inhibition and behavioral models of antidepressant, antiaggressive, and anxiolytic activity (for a review, see Sanchez *et al.* 2003). In these in vivo paradigms, escitalopram's potency ranges from being similar to that of citalopram to being approximately twofold greater than that of citalopram. In contrast, in the majority of these paradigms, *(R)*-citalopram is severalfold less potent than either escitalopram or citalopram.

Pharmacokinetics and Disposition

Citalopram

Citalopram is well absorbed after oral administration, with an absolute bioavailability of 80% for citalopram tablets (Joffe *et al.* 1998). The peak plasma concentration is normally observed 2-4 hours after an oral dose (Kragh-Sorensen *et al.* 1981). The bioavailability of citalopram is not affected by food (Baumann 1992), and it is subject to very little first-pass metabolism (Kragh-Sorensen *et al.* 1981). The apparent volume of distribution is 12-16 L/kg (Fredricson Overo 1982; Kragh-Sorensen *et al.* 1981), which indicates that the drug distributes widely. There is a linear relationship between steady-state plasma concentration and dose (Bjerkenstedt *et al.* 1985), and plasma protein binding is about 80% (Baumann 1992). Systemic clearance of citalopram is 0.3-0.4 L/minute (Baumann 1992), and renal clearance of citalopram is approximately 0.05-0.08 L/minute (Sindrup *et al.* 1993).

Racemic citalopram undergoes *N*-demethylation by the hepatic cytochrome P450 (CYP) system to the major metabolite monodesmethylcitalopram (DCT). Enzymes CYP2C19, CYP3A4, and CYP2D6 all contribute approximately equally to the formation of DCT (Kobayashi *et al.* 1997; Rochat *et al.* 1997; von Moltke *et al.* 1999). DCT also undergoes *N*-demethylation to the minor metabolite didesmethylcitalopram by the actions of CYP2D6 (Sindrup *et al.* 1993; von

Moltke *et al.* 2001). Clinical studies indicate that the half-lives for citalopram, DCT, and didesmethylcitalopram are approximately 36, 50, and 100 hours, respectively (Dalgaard and Larsen 1999; Fredricson Overo 1982; Kragh-Sorensen *et al.* 1981). Citalopram is metabolized by human cytochromes that display genetic polymorphisms, and metabolism of citalopram and DCT is impaired in patients who show poor metabolism via the CYP2C19 and CYP2D6 pathways (Baumann *et al.* 1996; Sindrup *et al.* 1993; Yu *et al.* 2003).

Escitalopram

The clinical pharmacokinetics of escitalopram were reviewed by Rao (2007). The clearance of *(S)*- and *(R)*-citalopram differs, such that the levels of the *(R)*-enantiomer are higher than the *(S)*-enantiomer when racemic citalopram is given. Therefore, doses of citalopram and escitalopram are not 2:1 (Brosen and Naranjo 2001)--that is, citalopram 20 mg has lower amounts of escitalopram than when escitalopram 10 mg is administered. This variation may account for some of the modest differences in clinical outcomes mentioned earlier (Auquier *et al.* 2003). Escitalopram has 56% protein binding, making it safer to administer with other drugs that are highly protein bound than citalopram (Rao 2007).

Mechanism of Action

The majority of studies on mechanism of action have focused on citalopram, with a relatively limited number of studies using escitalopram. Because the antidepressant activity of citalopram results from escitalopram, the majority of the conclusions from these studies pertain to both medications.

Citalopram is a potent and selective inhibitor of serotonin reuptake and acts by binding directly to the serotonin transporter. Citalopram more selectively inhibits radioligand binding to the serotonin transporter (K_i = 0.75 nM) than to the norepinephrine transporter (K_i = 3,042 nM) in rat cortical membranes. A similar selectivity was found for inhibition of the binding of the same radioligands to the cloned human serotonin and norepinephrine transporters expressed in transfected cells and for inhibition of [3H]-serotonin (K_i = 8.9 nM) and [3H]-norepinephrine (K_i = 30,285 nM) reuptake into these transfected cells (Owens *et al.* 1997).

Several studies have described how repeated dosing alters the effects of citalopram on serotonergic neuronal function. As with other SSRIs, the ability of citalopram to inhibit the firing of serotonin neurons in the dorsal raphe nucleus is greatly reduced after 14 days of repeated administration (Chaput *et al.* 1986). This change is associated with an increase in the ability of citalopram to elevate the extracellular levels of serotonin in the cortex (Invernizzi *et al.* 1994). These two effects appear to result from a desensitization of serotonin_{1A} autoreceptors (Chaput *et al.* 1986; Cremers *et al.* 2000; Invernizzi *et al.* 1994). This adaptive change of serotonin_{1A} receptors after repeated administration of citalopram, or other SSRIs, has been postulated to underlie the slow onset of antidepressant efficacy that is observed clinically (Blier and de Montigny 1994).

Evidence suggests that a variety of antidepressants, including those that block monoamine reuptake or metabolism, produce their therapeutic response in part by overcoming depression-associated decreases in neurogenesis and synaptogenesis, which is likely to be the result of effects on brain-derived neurotrophic factor (BDNF) expression, and possibly other neurotrophins such as vascular endothelial growth factor (Deyama *et al.* 2019). Citalopram, like many other antidepressants, has been shown to increase the levels of BDNF messenger RNA (mRNA) in various subregions of the rat ventral hippocampus (Russo-Neustadt *et al.* 2004) and to induce signaling through the BDNF receptor tyrosine kinase receptor TrkB (Rantamaki *et al.* 2007). In addition, citalopram was shown to enhance BDNF expression in neural crest-derived PC12 cells and enhance cell survival (Tan *et al.* 2010). Both citalopram and escitalopram were shown to increase peripheral blood BDNF in human patients with MDD (Zhou *et al.* 2017), an effect that has been shown with many antidepressants. Like other antidepressants, BDNF synthesis, release, and downstream actions on neurogenesis and synaptogenesis appear to be important targets of citalopram and escitalopram (Duman and Duman 2015).

A number of studies have implicated the serotonin$_{2A}$ (5-HT$_{2A}$) receptor in a variety of neuropsychiatric disorders (Norton and Owen 2005), and there is evidence implicating this receptor in the mechanism of action of antidepressants, including citalopram (Chen and Lawrence 2003; Peremans *et al.* 2005). In addition, a large-scale clinical study involving 1,953 patients who participated in the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial identified a significant association between a polymorphism contained in the second intron of the gene for the 5-HT$_{2A}$ receptor (rs7997012) and treatment response to citalopram, although the absolute effect was small (McMahon *et al.* 2006).

Several cellular and in vivo animal model studies have shown that antidepressants can increase glucocorticoid receptor (GR) translocation, induce GR downregulation, and decrease GR agonist-mediated effects (Anacker *et al.* 2011; Carvalho and Pariante 2008), and there is evidence suggesting that similar effects occur in vivo in humans. In a double-blind, placebo-controlled, crossover study in healthy men, treatment for 4 days with citalopram 20 mg/day was associated with a diminished ability of cortisol to increase electroencephalogram alpha power and to impair working memory (Pariante *et al.* 2012). These results suggest that GR activation by antidepressants does occur in the human brain.

Corticotropin-releasing factor (CRF) mediates many of the effects of psychological stress and is postulated to play a role in the pathophysiology of depression and anxiety disorders (Arborelius *et al.* 1999). In rats, lentiviral-mediated chronic elevation of amygdala CRF reproduces many of the behavioral and endocrine consequences of chronic stress that are consistent with a depressive or anxious phenotype (Flandreau *et al.* 2012). Interestingly, chronic escitalopram treatment of these CRF-overexpressing rats for 4 weeks reversed some but not all of the CRF-induced anxiety-like and depressive-like behavioral alterations (Flandreau *et al.* 2013).

Indications and Efficacy

Depression

Citalopram

The efficacy of citalopram (dosage range, 20-80 mg/day) in the treatment of depression has been shown in at least 11 placebo-controlled clinical trials (for a review, see Keller 2000). In addition, meta-analyses of multiple placebo-controlled studies reported similar findings (Bech and Cialdella 1992; Montgomery *et al.* 1994). In the United States, three large multicenter registration clinical trials demonstrated citalopram's efficacy in the treatment of MDD (Feighner and Overo 1999; Mendels *et al.* 1999; Stahl 2000). Primary care patients in the United Kingdom were given citalopram 20 mg/day (*n* = 274) or the norepinephrine reuptake inhibitor reboxetine 4 mg tid (*n* = 272); both medications were equally effective in the treatment of severe depression (defined as a Beck Depression Inventory score of 15 or greater) (Wiles *et al.* 2012). One large-scale meta-analysis reported that the efficacy of both citalopram and escitalopram was equal to that of other drugs, but both were more tolerable than many other drugs (Cipriani *et al.* 2018). As noted earlier, the analysis reported that escitalopram may be more effective than citalopram. Overall, there is ample evidence of acceptable efficacy and tolerability of citalopram.

Sequenced Treatment Alternatives to Relieve Depression trial.

The effectiveness of citalopram was also demonstrated in a study designed to simulate real-world conditions for the treatment of depression. STAR*D was a large-scale multicenter study that enrolled 4,041 patients with nonpsychotic MDD in a test of various antidepressant therapies (Rush *et al.* 2004). The mean dosage of citalopram at study exit was 41.8 mg/day. Remission rates were 28% when remission was defined as a score of 7 or less on the 17-item version of the Hamilton Rating Scale for Depression (Ham-D) and 33% when defined as a score of 5 or less on the 16-item Quick Inventory of Depressive Symptomatology-Self-Report (QIDS-SR) (Trivedi *et al.* 2006). The response rate was 47% when response was defined as a50% or greater reduction in QIDS-SR score (Trivedi *et al.*

2006). These response and remission rates are comparable to those found in 8-week controlled clinical trials examining the efficacy of acute antidepressant treatment.

Long-term treatment with citalopram. Two placebo-controlled studies indicated that citalopram may be effective in continuation therapy to prevent depression relapse (Montgomery *et al.* 1993; Robert and Montgomery 1995). Both studies showed that for patients with an acute therapeutic response to citalopram, continuation of citalopram therapy at the same dosage (20, 40, or 60 mg/day) for an additional 24 weeks significantly decreased the relapse rate compared with placebo (Montgomery *et al.* 1993; Robert and Montgomery 1995). Two additional studies suggested that citalopram may be beneficial for patients with a history of recurrent depression. Long-term (at least 48 weeks) administration of citalopram at the same fixed dosage at which patients initially showed therapeutic response (20-60 mg/day) can significantly increase the time before depression recurs in adult patients (ages 18-64 years) and in elderly patients (age 65 years and older) (Hochstrasser *et al.* 2001; Klysner *et al.* 2002).

Escitalopram

A number of placebo-controlled clinical trials and retrospective analyses have demonstrated the efficacy of escitalopram (dosage range, 10-20 mg/day) in the treatment of MDD (Burke *et al.* 2002; Lepola *et al.* 2003; Montgomery *et al.* 2001; Wade *et al.* 2002). In addition, a large number of retrospective pooled analyses have compared escitalopram with other SSRIs (Einarson 2004; Kennedy *et al.* 2006; Llorca *et al.* 2005). In general, escitalopram was at least as effective as other widely used antidepressants; in some clinical trials, escitalopram was suggested to be superior to other antidepressants based on modestly greater score changes on various depression rating scales, especially for patients with severe depression. In addition, escitalopram has been suggested in a few clinical trials to possibly have a faster onset of therapeutic effect (based on changes in depression rating scale scores), occurring as early as week 1, as indicated by a small but significant difference in depression severity ratings, as contrasted with comparator drugs (Auquier *et al.* 2003). It is unlikely that the small differences early in treatment translate into improved early results in clinical practice.

Long-term treatment with escitalopram. In a 36-week placebo-controlled clinical trial, participants given escitalopram 10-20 mg/day (*n* = 181) were less likely to experience relapse after resolution of a depressive episode than were those given placebo (*n* = 93) (Rapaport *et al.* 2004). In addition, the effectiveness of long-term escitalopram therapy in the prevention of depression recurrence was also demonstrated in a group of patients diagnosed with recurrent MDD (Kornstein *et al.* 2006). Patients given escitalopram 10 or 20 mg/day (*n* = 73) in this 52-week study had a significantly prolonged time to recurrence compared with those given placebo (*n* = 66).

International Study to Predict Optimized Treatment in Depression.

Treatment of depression may be significantly improved with the discovery of biomarkers that can identify which patients will respond best to which treatments. For example, depression is associated with impairments in a wide range of cognitive and emotional functioning (Snyder 2013). The International Study to Predict Optimized Treatment in Depression (iSPOT-D) trial was intended to determine whether laboratory measures of impaired functioning can be used to predict antidepressant treatment outcomes. In one report, medication-free outpatients with nonpsychotic MDD (*n* = 665 completers) were assessed before treatment with 13 computerized tests of cognitive and emotional functioning, and their performance was compared with that of healthy control subjects (*n* = 336). Patients were then randomly assigned to receive 8 weeks of treatment with escitalopram, sertraline, or extended-release venlafaxine (Etkin *et al.* 2015). Approximately one-quarter of patients had significant impairment across most cognitive tests relative to healthy control subjects, and these patients had poorer treatment outcomes. Worse cognitive task performance was associated with lower rates of remission (based on scores on the 16-item QIDS-SR), with 72%

accuracy for treatment with escitalopram but not for treatment with the other antidepressants. Among the patients predicted to be nonresponders, the greatest impairments were on tests of attention, decision speed, working memory, and speed of emotion identification. Those predicted to not achieve remission with escitalopram had a slightly higher score on the Ham-D (23.3 vs. 21.5). One interpretation of the results is that individuals with a greater level of cognitive impairment due to depression have poorer outcomes, which is not surprising. However, it does suggest that SSRI monotherapy, particularly with a highly selective serotonin reuptake inhibitor, may not be the best choice for patients with significant cognitive problems associated with depression.

Neuroimaging studies have also focused on identifying patterns of brain activation that may be predictive of antidepressant treatment outcomes. Previous functional MRI studies demonstrated that activation of the right lateral and medial prefrontal cortices and limbic regions during inhibitory responses on the go/no-go task predicted a greater treatment response to escitalopram (Langenecker *et al.* 2007). A similar approach was described in a study from the iSPOT-D trial that involved 80 medication-free outpatients with MDD and 34 matched healthy control subjects (Gyurak *et al.* 2016). During the functional MRI scans, patients completed three tasks to assess core domains of cognitive function. They then received 8 weeks of antidepressant treatment, functional MRI scans were repeated, and depression remission was assessed with Ham-D scores. Intact activation of the frontoparietal network during inhibitory no-go responses predicted remission, particularly for individuals given the SSRIs escitalopram and sertraline. During the no-go responses, remitters showed the same pretreatment dorsolateral prefrontal cortex activation as control subjects, and nonremitters showed hypoactivation relative to control subjects. These study findings hold promise for identifying biomarkers that can help predict which patients are most likely to respond to citalopram and escitalopram treatment.

Genome-Based Therapeutic Drugs for Depression study. A genome-based approach to identifying genes associated with therapeutic response to escitalopram has also yielded interesting findings. As part of the Genome-Based Therapeutic Drugs for Depression (GENDEP) study, genome-wide association analysis examined 539,391 single-nucleotide polymorphisms to identify genes that underlie individual differences in antidepressant treatment response. The partially randomized, single-blind study examined DNA from unrelated patients of European ancestry assigned to receive 12 weeks of treatment with either escitalopram 10-30 mg/day (n = 394) or nortriptyline 50-150 mg/day (n = 312). Although no marker was associated at a genome-wide level of significance, escitalopram response was predicted at a suggestive level of significance ($P = 0.00049$) by a synonymous single-nucleotide polymorphism (rs1126757) in interleukin gene *IL11* (Uher *et al.* 2010). In addition, a targeted analysis of 72 a priori selected candidate genes identified an association between escitalopram response and a single-nucleotide polymorphism (rs7801617) in the gene encoding *IL6*, a close homolog of *IL11*. A follow-up epigenetic study examined variations in DNA methylation of *IL11* as predictors of antidepressant treatment response using a subset of participants randomly selected from the GENDEP study who received either escitalopram (n = 80) or nortriptyline (n = 33) (Powell *et al.* 2013). This study reported that DNA methylation levels on some cytosine-phosphate-guanine (CpG) islands predicted antidepressant treatment response and that an interaction between CpG island methylation and genotype at rs1126757 could also predict treatment response. These studies are some of the first to provide evidence that a genomic approach may be fruitful for identifying molecular biomarkers that can predict which patients will best respond to specific antidepressants. However, as with the associations of the 5-HT$_{2A}$ variants noted earlier (see "Mechanism of Action" section), the ultimate predictive power of methylation of rs1126757 was low.

Another investigation from the GENDEP study sought to identify gene expression differences present prior to treatment that could predict treatment response. This study examined leukocyte mRNA expression in healthy control subjects (n = 34) and patients with depression (n = 74) before and after 8 weeks of treatment with escitalopram or nortriptyline (Cattaneo *et al.* 2013). The analysis was limited to 15 candidate genes that belonged to one of three groups previously implicated in the pathogenesis of depression or putative mechanisms of action of antidepressants (GR function, inflammation, and neuroplasticity). Regarding predictors present prior to treatment, nonresponders had higher mRNA levels for *IL1*b (+ 33%), macrophage inhibiting factor (+ 48%), and tumor necrosis factor (+ 39%). A similar study using a nonoverlapping set of GENDEP subjects and focusing only on escitalopram treatment also found higher mRNA levels for tumor necrosis factor (+ 20%) in nonresponders (Powell *et al.* 2013).

A second aim of the study by Cattaneo *et al.* (2013) was to identify changes in gene expression occurring during the course of successful treatment that could point to potential targets of drug action. Successful antidepressant treatment was associated with increases in mRNA levels for *BDNF* (+ 48%) and VGF nerve growth factor inducible (+ 20%) as well as modest reductions in mRNA levels for *IL6* ([?] 9%) and FK506 binding protein 5 ([?] 11%). Taken together, these data indicate that the genes thought to serve as predictors of antidepressant response may be separate from the genes hypothesized to be altered by successful treatment. The authors also noted that with the exception of *IL6*, all gene expression differences were in the same direction for both escitalopram and nortriptyline despite their different mechanisms of action, suggesting that these gene expression changes reflect alterations in pathways common to the two antidepressants and not pathways selective to serotonergic or adrenergic neurotransmission (Cattaneo *et al.* 2013).

Combining Medications to Enhance Depression Outcomes Trial and related combination treatment trials.

There is strong evidence that most, or possibly all, effective antidepressant treatments target a limited set of mechanisms that involve actions on neurotrophins, resulting in the formation of regulatory synapses between neurons (Duman and Duman 2015). However, the path to those mechanisms varies considerably between medications. The SSRIs block the reuptake of serotonin, selective norepinephrine reuptake inhibitors do so for norepinephrine, bupropion increases synaptic norepinephrine and dopamine, and medications such as mirtazapine and vortioxetine block specific serotonin receptors. Therefore, combining medications could enhance the downstream effects. A commonly used treatment is the combination of SSRIs and bupropion. An important question, then, has been whether combining antidepressants with different mechanisms could either speed response or increase the rate of remission.

In an early test of this hypothesis, Nelson *et al.* (2004) found that a combination of fluoxetine 20 mg/day plus desipramine (a relatively selective norepinephrine reuptake inhibitor) dosed to achieve an adequate blood level was superior to either fluoxetine or desipramine monotherapy. Blier *et al.* (2009) compared the relative effectiveness of paroxetine, mirtazapine, or their combination in patients with MDD. The combination treatment produced a substantially higher remission rate at 6 weeks (43%) than either mirtazapine (19%) or paroxetine (26%) monotherapy. In a subsequent study, this same group reported that the combination of escitalopram and bupropion produced higher rates of remission. Combinations of citalopram and bupropion or venlafaxine plus mirtazapine were also tested in the STAR*D trial described earlier (see "Mechanism of Action" section) (Rush *et al.* 2006). These combinations were effective, but not more so than monotherapies at the same level of care. The STAR*D trial was followed by the Combining Medications to Enhance Depression Outcomes Trial (CO-MED), which compared escitalopram (up to 20 mg/day), sustained-release bupropion (up to 400 mg/day) plus escitalopram, and the combination of venlafaxine and mirtazapine as initial treatment in patients with moderate to severe MDD (N = 665). Response and remission rates at 12 weeks and 7 months did not differ between groups, and side effects were worse for the venlafaxine plus mirtazapine group than

for escitalopram monotherapy. A criticism of CO-MED was that the dosing of medications was not optimal (the mean dose of mirtazapine was only 20 mg/day) and, in the case of escitalopram, varied between groups (Blier 2012). Given the flaws in CO-MED, there is no firm conclusion about the effectiveness of initial treatment with combined antidepressant medications. However, that should not necessarily detract from using combined antidepressants in difficult-to-treat depression (i.e., inadequate response to one or more antidepressant monotherapies).

Depression in Children and Adolescents

Fluoxetine is currently the only FDA-approved medication for the treatment of depression in both children and adolescents (ages 8 years and older). Escitalopram was approved in 2009 for the treatment of depression in adolescents (ages 12-17 years) but not in younger children. In addition, the FDA has mandated the placement of black box warnings on product labels to indicate the potential for increased suicidality associated with the use of SSRIs in patients younger than 25 years. Importantly, a meta-analysis of pediatric trials conducted between 1988 and 2006 indicated that the benefits of antidepressant treatment in the young outweigh the risks (Bridge *et al.* 2007).

Citalopram

Only a limited number of clinical studies have examined the effectiveness of citalopram in the treatment of depression in youth. In one double-blind trial involving 174 children and adolescents (ages 7-17 years), citalopram (20 mg/day) showed a modest superiority over placebo in the treatment of depression (Wagner *et al.* 2004). Conversely, citalopram (10-40 mg/day) was not superior to placebo in a clinical trial involving 244 adolescents (ages 13-18 years) receiving treatment for 12 weeks (von Knorring *et al.* 2006). Clearly, additional clinical trials are required to establish the efficacy and safety of citalopram in the treatment of childhood depression.

Escitalopram

Several studies have addressed the effectiveness of escitalopram in the pediatric population. Escitalopram was shown to be effective in the treatment of depression in adolescents (ages 12-17 years) in a randomized, double-blind, placebo-controlled multicenter clinical trial (Emslie *et al.* 2009). In this study, the group given escitalopram 10-20 mg/day ($n = 155$), compared with the group given placebo ($n = 157$), had greater improvement based on change from baseline to week 8 in scores on the Children's

Depression Rating Scale-Revised (CDRS-R). In another randomized double-blind trial investigating treatment of MDD in children and adolescents (ages 6-17 years), those given escitalopram 10-20 mg/day (n = 131) did not improve significantly more than those given placebo (n = 133). However, in a post hoc analysis of just the adolescents (ages 12-17 years), those given escitalopram (n = 80), compared with placebo (n = 77), had significantly more improved CDRS-R scores from baseline to week 8 (Wagner *et al.* 2006). Finally, the long-term benefits of escitalopram treatment for depression in adolescents were demonstrated in an extension trial that enrolled a subset of the sample participating in the aforementioned Emslie *et al.* (2009) study. This double-blind 16-to 24-week trial (Findling *et al.* 2013) showed that in comparison with subjects given placebo (n = 40), those given escitalopram 10-20 mg/day (n = 37) showed a modest but statistically significantly greater improvement in CDRS-R scores from baseline on the lead-in study to treatment week 24 (8-week lead-in study plus 16-week extension) (P = 0.005).

Generalized Anxiety Disorder

Citalopram

One small case series indicated that citalopram might be effective in generalized anxiety disorder (Varia and Rauscher 2002). However, no large-scale randomized, double-blind clinical trials have examined the effectiveness of citalopram in the treatment of this disorder. As described next, all large-scale trials have focused on the use of escitalopram in the treatment of generalized anxiety disorder.

Escitalopram

The efficacy of escitalopram in the treatment of generalized anxiety disorder has been established in several randomized controlled clinical trials (Baldwin and Nair 2005). Escitalopram's effectiveness in acute treatment of generalized anxiety disorder was shown in three double-blind, placebo-controlled clinical trials that were also subjected to pooled analysis. These studies demonstrated that escitalopram (10-20 mg/day administered for 8-12 weeks) was superior to placebo (Davidson *et al.* 2004; Goodman *et al.* 2005; Stein *et al.* 2005). The efficacy of escitalopram (10-20 mg/day) in the long-term treatment of generalized anxiety disorder was demonstrated in two 24-week controlled clinical trials, one open label (Davidson *et al.* 2005) and the other double blind (Bielski *et al.* 2005). Escitalopram also showed efficacy in the prevention of generalized anxiety disorder relapse for an additional 24-76 weeks (Allgulander *et al.* 2006). Escitalopram received FDA approval for generalized anxiety disorder in 2003.

Panic Disorder

Citalopram

Few well-controlled studies have evaluated the effectiveness of citalopram in the treatment of panic disorder. In a 1-year placebo-controlled, double-blind study of 279 patients who agreed to continue treatment after an acute period during which they were randomly assigned to citalopram (20 or 30 mg/day vs. 40 or 60 mg/day), clomipramine (60 or 90 mg/day), or placebo, all drug-treated groups showed significantly greater improvement compared with placebo on a variety of anxiety rating instruments, including the Clinical Anxiety Scale panic attack item. The authors concluded that citalopram at a dosage range of 20-60 mg/day was an effective long-term therapy for the management of panic disorder (Lepola *et al.* 1998).

Escitalopram

Escitalopram 5-10 mg/day was shown to be effective in the treatment of panic disorder in a 10-week randomized, double-blind, placebo-controlled, flexible-dosage study in patients with a diagnosis of panic disorder with or without agoraphobia (Stahl *et al.* 2003). Relative panic attack frequency was significantly lower in the escitalopram group (n = 125) than in the placebo group (n = 114). At the end of the study, a greater proportion of patients had zero panic attacks in the escitalopram group (50%) than in the placebo group (38%) ($P = 0.051$).

Social Anxiety Disorder

Citalopram

A large-scale, double-blind, placebo-controlled study demonstrated that paroxetine is effective for social anxiety disorder, suggesting that some SSRIs may be effective for this disorder (Stein *et al.* 1998). Despite the lack of large-scale, placebo-controlled studies using citalopram, case reports indicate that citalopram may be effective in the treatment of social anxiety disorder (Bouwer and Stein 1998; Lepola *et al.* 1994; Simon *et al.* 2001). In addition, one 12-week small-scale (*n* = 21), flexible-dose open-label study demonstrated the effectiveness of citalopram (20-60 mg/day) in relieving the symptoms of social anxiety disorder in patients with comorbid depression (Schneier *et al.* 2003).

Escitalopram

Two large-scale, multinational, multicenter clinical trials have demonstrated the effectiveness of escitalopram in the treatment of social anxiety disorder. In a 24-week fixed-dosage trial in patients with a diagnosis of social anxiety disorder, escitalopram at three dosages (5 mg/day, *n* = 167; 10 mg/day, *n* = 167; or 20 mg/day, *n* = 170) and paroxetine (20 mg/day, *n* = 169) each showed a statistically superior therapeutic effect compared with placebo (*n* = 166) by week 12 (Lader *et al.* 2004). Further improvement was seen by week 24 for all dosages of escitalopram and for paroxetine, and escitalopram 20 mg/day was superior to paroxetine 20 mg/day. In a 12-week study, escitalopram 10-20 mg/day (*n* = 181) produced a superior therapeutic response compared with placebo (*n* = 177) based on mean change in Liebowitz Social Anxiety Scale score from baseline (Kasper *et al.* 2005). Similar results were found in a large-scale study (*N* = 588) conducted in Japan (Asakura *et al.* 2016). In a long-term study, escitalopram treatment at a dosage of 10 or 20 mg/day for up to 24 weeks was shown to be effective in preventing relapse of social anxiety disorder after successful short-term therapy, with relapse being 2.8 times more likely with placebo treatment (*n* = 181) than with escitalopram treatment (*n* = 190) (Montgomery *et al.* 2005).

Anxiety Associated With Major Depressive Disorder

Citalopram

A retrospective study of 2,000 patients with depression enrolled in eight double-blind, placebo-controlled clinical trials revealed that citalopram was effective in relieving anxiety symptoms in patients with depression based on a greater decrease from baseline in the Ham-D anxiety factor (Flicker *et al.* 1998). The antidepressant effect in that study was equivalent in patients with MDD with higher and lower levels of anxiety. Another double-blind, placebo-controlled study in 323 patients with a diagnosis of MDD revealed a significant antianxiety effect of citalopram 20-60 mg/day compared with placebo based on decreases in Hamilton Anxiety Scale scores (Stahl 2000). In neither study was the effect on anxiety symptoms shown to be independent of improvements in depression, suggesting that the benefits were syndromic with regard to the depressive disorder.

Escitalopram

The effectiveness of escitalopram in the treatment of anxiety symptoms associated with MDD was evaluated in a pooled analysis of five clinical trials (Bandelow *et al.* 2007). These placebo-controlled trials were originally designed to examine the effectiveness of

escitalopram in treating MDD. In the pooled analysis, escitalopram 10-20 mg/day (*n* = 850) was consistently superior to placebo (*n* = 737) in relieving anxious symptoms associated with depression, as evaluated with several different assessments of anxiousness. The analyses presented in this pooled study indicate that escitalopram is effective in relieving anxiety symptoms in patients with depression. Like citalopram, there was not an independent effect on change in anxiety severity relative to change in depression.

Obsessive-Compulsive Disorder

Citalopram

To date, a limited number of clinical studies have evaluated the effectiveness of citalopram in the treatment of OCD. In the only published large-scale (*N* = 401), double-blind, placebo-controlled study of citalopram in the treatment of OCD, all three dosages of citalopram (20, 40, and 60 mg/day) given for 12 weeks were significantly more effective than placebo in relieving OCD symptoms (Montgomery *et al.* 2001). Another trial compared citalopram (60 mg/day) plus quetiapine (300-450 mg/day) with citalopram monotherapy (*N* = 76) and found that combined treatment was more effective than monotherapy. A secondary analysis of a clinical trial comparing citalopram with placebo identified five symptom clusters from the Yale-Brown Obsessive Compulsive Scale: contamination/cleaning, harm/checking, aggressive/sexual/religious, hoarding/symmetry, and somatic/hypochondria. Citalopram was more effective than placebo in reducing scores on most dimensions; patients who initially scored high on the hoarding/symmetry and contamination/cleaning factors did less well with citalopram. By contrast, people who initially scored higher on the aggressive/sexual/religious subscale did better with citalopram (Stein *et al.* 2007a). The relatively lower effect in patients with high hoarding scores is consistent with some prior research with SSRIs (Mataix-Cols *et al.* 1999).

Escitalopram

The effectiveness of escitalopram in the treatment of OCD was demonstrated in a 24-week double-blind, placebo-controlled, multicenter clinical trial (Stein *et al.* 2007b). In this study, escitalopram 20 mg/day (*n* = 116) and paroxetine 40 mg/day (*n* = 119) produced significant improvement compared with placebo; by week 24, all treatments, including escitalopram 10 mg/day (*n* = 116), were superior to placebo (*n* = 115). Long-term treatment with escitalopram was shown in one large-scale study to prevent relapse of OCD in patients who had responded to initial treatment (Fineberg *et al.* 2007). Patients treated with escitalopram 10 or 20 mg/day (*n* = 163) showed a significantly greater time to relapse compared with those receiving placebo (*n* = 157). A small randomized study found no differences between escitalopram and sertraline for OCD (Mowla *et al.* 2018).

Investigational Uses

Stress-Induced Myocardial Ischemia

Escitalopram

Substantial evidence implicates emotional stress as a trigger of acute coronary syndromes, and this effect can be reproduced in laboratory settings. Studies show that up to

70% of patients with stable coronary heart disease display mental stress-induced myocardial ischemia (MSIMI) (Strike and Steptoe 2003). The Responses of Mental Stress-Induced Myocardial Ischemia to Escitalopram Treatment (REMIT) study was designed to determine whether SSRI treatment could improve heart function after mental stress in patients with laboratory-diagnosed MSIMI. At the end of this 6-week randomized, double-blind, placebo-controlled study, significantly more patients receiving escitalopram treatment (*n* = 56; 5 mg/day titrated to 20 mg/day over 3 weeks) showed no MSIMI during three mental stressor tasks than those receiving placebo (*n* = 56) (OR, 2.62; 95% CI, 1.06-6.44; *P* = 0.04) (Jiang *et al.* 2013). There was no statistically significant effect for exercise-induced ischemia in the REMIT study. These results offer a preliminary indication of the potential utility of SSRIs in preventing mental stress-induced acute coronary syndromes.

Alzheimer's Disease

Citalopram

Brain accumulation of amyloid plaques formed by the aggregation of the amyloid-b peptide (Ab) is thought to be central to the pathophysiology of

Alzheimer's disease (Holtzman *et al.* 2011). The aggregation of Ab into plaques is concentration dependent (Bero *et al.* 2011; Lomakin *et al.* 1997); therefore, methods to decrease Ab levels may be therapeutic. Previous studies have shown that serotonin signaling suppresses the generation of Ab in vitro and in animal models of Alzheimer's disease (Cirrito *et al.* 2011; Nitsch *et al.* 1996). In an aged transgenic Alzheimer's disease mouse model (APP/PS1 plaque-bearing mice), acute citalopram treatment led to a dose-dependent decrease in brain interstitial fluid Ab levels, and chronic citalopram treatment arrested the growth of preexisting plaques and reduced the appearance of new plaques by 78% (Sheline *et al.* 2014). In addition, acute administration of citalopram (60 mg/day) in 23 healthy humans (ages 18-50 years; 11 female participants) in a double-blind study resulted in lower cerebrospinal fluid Ab production (37%) and concentration (38%) compared with placebo (Sheline *et al.* 2014). A similar effect was shown in aged mice with Alzheimer's disease. These results were supported in both mice and humans with other SSRIs (Cirrito *et al.* 2011). To the extent that Alzheimer's disease involves the accumulation of Ab, these results suggest a potential role for SSRI treatment in the prevention of Alzheimer's disease, and future studies should be aimed at defining the mechanism by which SSRI treatment lowers Ab levels.

Side Effects and Toxicology

Citalopram

In a meta-analysis of 746 patients with depression involved in several short-term clinical trials, the most common adverse events associated with citalopram were nausea and vomiting (20%), increased sweating (18%), and dry mouth and headache (17%) (Muldoon 1996). Analysis of an integrated safety database, which included data from 3,107 patients enrolled in 24 clinical trials, indicated that in placebo-controlled trials, nausea, dry mouth, somnolence, increased sweating, tremor, diarrhea, and ejaculatory failure of mild to moderate severity occurred with significantly greater frequency in patients given citalopram than in those given placebo (Muldoon 1996). The incidence of these adverse events with citalopram was less than 10% above that seen with placebo and was comparable to that reported with other SSRIs. Citalopram had a tolerability that was superior to that of the tricyclic antidepressants, with the exception that nausea and ejaculatory failure occurred with a 5% greater frequency in patients given citalopram (Keller 2000).

Escitalopram

In general, the side effects associated with escitalopram are similar to those observed with citalopram. In three placebo-controlled clinical trials performed with escitalopram, rates of discontinuation because of adverse events did not differ for patients given 10 mg/day compared with those administered placebo (Burke *et al.* 2002; Montgomery *et al.* 2001; Wade *et al.* 2002). In the trial that included an escitalopram dosage of 20 mg/day, the rate of discontinuation was 10.4% for the escitalopram-treated group versus 2.5% for the placebo-treated group (Burke *et al.* 2002). In addition, the rate of adverse events overall in the group receiving escitalopram 20 mg/day (85.6%) was significantly greater than that in the placebo group (70.5%). Regardless of dosage, the adverse events reported to occur more frequently with escitalopram compared with placebo are nausea, diarrhea, insomnia, dry mouth, and ejaculatory disorder, with nausea being reported most frequently at a rate of 15% (McRae 2002). To date, no published studies have reported clinically significant findings in laboratory test values, vital signs, weight gain or loss, or electrocardiogram values. Notably, sexual side effects in registration trials of citalopram and escitalopram (as well as other SSRIs) relied on self-report, which was likely to have underestimated the actual rate. Complaints of loss of libido, erectile dysfunction, and anorgasmia are common in patients treated with SSRIs. Sexual satisfaction tends to be low in the majority of patients with MDD and, even with SSRIs, improves with remission, although it tends to worsen for patients with nonremitting depression (Clayton *et al.* 2007; Ishak *et al.* 2013). Low sexual satisfaction and particularly worsened satisfaction may be an indicator of nonremission in SSRI-treated patients.

Specific Effects and Syndromes

QT Interval Prolongation

Citalopram is associated with a dose-dependent prolongation of the electrocardiographic corrected QT (QTc) interval, which can increase the risk of a potentially fatal abnormal heart rhythm called torsades de pointes, a type of polymorphic tachycardia. As a result, the FDA recommended that citalopram not be prescribed at dosages greater than 40 mg/day for most adults or greater than 20 mg/day for patients older than age 60 years (Medical Letter on Drugs and Therapeutics 2013; U.S. Food and Drug Administration 2017). In addition, citalopram use should be avoided in populations at increased risk for QTc interval prolongation, such as patients with congenital long QT syndrome. For at-risk patients for whom no satisfactory alternatives to citalopram are available, a low citalopram dosage should be used and electrocardiograms and/or electrolytes should be monitored. However, given the number of SSRIs currently available, citalopram should be avoided for higher-risk patients. Citalopram should be discontinued for patients with a QTc interval greater than 500 milliseconds. As in any clinical situation, the clinician must weigh the risk/benefit ratio for the treatment. In some cases, it may be reasonable to use dosages that exceed the FDA guidelines for patients with a lower risk for adverse effects. Importantly, escitalopram at dosages therapeutically equivalent to those of citalopram has not been demonstrated to significantly affect the QTc interval in most trials. However, one study in healthy control subjects (*N* = 40) reported a modest average increase of 10.5 milliseconds in patients treated with escitalopram 20 mg/day (Kim *et al.* 2016). This level of QTc prolongation is not considered clinically serious (Shah 2002). Escitalopram was also evaluated in a 24-week study in patients with depression and acute coronary syndrome; the escitalopram group had a lower rate of major adverse cardiac events relative to placebo-treated patients (Kim *et al.* 2018).

Hyponatremia

Citalopram and escitalopram have been shown to produce hyponatremia in case reports involving elderly patients, and this information has been reviewed elsewhere (Jacob and Spinler 2006). In addition to advanced age, other factors that may increase the likelihood of hyponatremia include female sex, concurrent diuretic use, low body weight, and recent pneumonia. Treatment of SSRI-induced hyponatremia usually involves fluid restriction and/or administration of a loop diuretic such as furosemide and may include discontinuation of the SSRI.

Discontinuation Syndrome

The abrupt cessation of antidepressant therapy can result in a discontinuation syndrome characterized by dizziness, nausea, vomiting, lethargy, and flulike symptoms (Shelton 2006). This syndrome is more common with shorter-half-life SSRIs or serotonin-norepinephrine reuptake inhibitors (e.g., paroxetine or venlafaxine) and is less common with longer-half-life SSRIs (e.g., fluoxetine). The data obtained from clinical trials suggest that the adverse events associated with discontinuation of citalopram or escitalopram tend to be mild and transient (Baldwin *et al.* 2007; Markowitz *et al.* 2000; Montgomery *et al.* 1993). However, dosage tapering rather than abrupt discontinuation is recommended for patients stopping treatment. In addition, patients should be warned of discontinuation symptoms during treatment should they miss doses or stop abruptly during treatment or when the medication is being tapered.

Treatment-Emergent Suicidal Ideation and Suicide

Considerable attention has been focused in recent years on the possibility that antidepressant drugs, especially SSRIs, may lead to treatment-emergent suicidal ideation (TESI) and an increased risk of suicide among some patients, particularly at the onset of therapy (Jick *et al.* 2004). This issue is of great concern for young patients and was described previously (see "Depression in Children and Adolescents"). In the case of citalopram, analyses of data obtained from 17 controlled clinical trials involving 5,000 patients indicate that the group receiving citalopram had a lower rate of suicide compared with the groups receiving placebo, tricyclic antidepressants, or other SSRIs (Nemeroff 2003). The risk of suicide associated with escitalopram was evaluated from data contained in the Summary Basis of Approval reports obtained from the FDA

(Khan and Schwartz 2007). The study authors did not detect a significantly greater rate of suicide in the escitalopram group compared with either the citalopram or placebo group. A meta-analysis of the escitalopram clinical trials database--consisting of 2,277 escitalopram-treated patients and 1,814 placebo-treated patients--also yielded no indication that escitalopram increased suicidal behavior in individuals with MDD and anxiety disorders (Pedersen 2005).

Although the data do not indicate a significantly greater risk of suicide for patients receiving either citalopram or escitalopram compared with those receiving placebo, most antidepressant studies show that a limited number of patients will exhibit TESI on initiation of therapy. Family and twin studies provide some evidence of a genetic influence on suicidal behavior, and it has been postulated that TESI may also be genetically influenced. Interestingly, a study in patients participating in the STAR*D trial demonstrated a significant association between citalopram-induced TESI in men and polymorphisms near the gene encoding cyclic adenosine monophosphate response element binding protein (*CREB*) (Perlis *et al.* 2007). This protein is of great interest because it mediates the effects of second messengers on new gene transcription and has been implicated in antidepressant action and suicide (Dowlatshahi *et al.* 1998; Dwivedi *et al.* 2003a). An analysis of nine candidate genes in patients from the GENDEP study who received either escitalopram or nortriptyline identified polymorphisms in *BDNF* as being associated with TESI, and there was also a significant interaction between variants in *BDNF* and *TRKB*, which encodes the BDNF receptor (Perroud *et al.* 2009). A proposed role for the *BDNF* pathway in TESI is consistent with previous reports of lower levels of *BDNF* mRNA and protein in the hippocampus and prefrontal cortex of individuals who died from suicide and lower levels of BDNF protein in the plasma of those who attempted suicide (Dwivedi *et al.* 2003b; Karege *et al.* 2005; Kim *et al.* 2007). In addition, *CREB* is thought to control *BDNF* gene transcription, providing a functional link between these two genetic associations and TESI (Dwivedi *et al.* 2003a; Finkbeiner 2000).

Finally, in a genome-wide association study also using GENDEP study participants, the strongest association with TESI was found for a single-nucleotide polymorphism located 30 kb downstream of the gene encoding guanine deaminase (Perroud *et al.* 2012). Investigators also found two suggestive escitalopram-specific associations with TESI that were contained in the gene for voltage-gated potassium channel-interacting protein 4 and near the gene for elongation protein 3 homolog (Perroud *et al.* 2012). Although no definitive conclusions can be drawn from this study or other genetic studies until they are replicated with larger samples, these findings point to the possibility that genetic markers may be used in the future to predict not only treatment response but also vulnerabilities to the adverse effects of specific drugs.

Drug-Drug Interactions

The majority of a citalopram dose is metabolized in the liver (75%). Yet because multiple CYP enzymes (CYP2C19, CYP3A4, and CYP2D6) contribute equally to the metabolism of citalopram and escitalopram, inhibition of metabolism by another drug of any one of these enzymes is unlikely to significantly affect the overall metabolism of citalopram or escitalopram. Consistent with this, there are relatively few reports in the literature of drug-drug interactions involving citalopram or escitalopram. Similarly, a loss-of-function genetic variation in one or two enzymes is unlikely to affect overall metabolism much. By contrast, a gain-of-function genetic variant, such as having multiple copies of *CYP2D6*, can adversely affect blood levels (Shelton *et al.* 2020). Because of the possibility of a potentially fatal pharmacodynamic interaction resulting in serotonin syndrome, neither citalopram nor escitalopram (or any SSRI or serotonin-norepinephrine reuptake inhibitor) should be administered with or within 14 days of discontinuing a monoamine oxidase inhibitor.

Conclusion

Citalopram and escitalopram are highly selective serotonin reuptake inhibitors that are well tolerated and effective for the treatment of depression, with escitalopram also having proven efficacy in large-scale clinical trials in the treatment of generalized anxiety disorder. Although the use of citalopram and escitalopram in the treatment of other psychiatric conditions has not been as thoroughly studied, the few well-controlled trials completed to date suggest that both drugs may have a role in treating other disorders, including panic disorder, social anxiety disorder, anxiety associated with depression, and OCD. However, neither drug is FDA approved for these indications. Citalopram and escitalopram rank among the most commonly prescribed medications. An advantage of citalopram and escitalopram compared with some other common SSRIs is a relatively weak inhibition of liver CYP enzymes, which reduces the potential for adverse pharmacokinetic drug-drug interactions. Citalopram has lower, and escitalopram much lower, protein binding than other SSRIs, making them safer when used with highly protein-bound drugs (e.g., warfarin); however, they are not as safe as venlafaxine and desvenlafaxine, which have very low protein binding. In addition, because escitalopram does not share with citalopram a modest affinity for the histamine$_1$ receptor, it may have a lower potential for antihistaminergic side effects compared with citalopram, a difference that has yet to be demonstrated in a clinical trial. In terms of effects on cardiac function, escitalopram's risk of producing QT interval prolongation appears to be lower than that of citalopram, and careful monitoring must accompany citalopram use for patients at risk for QT prolongation. A number of clinical trials have compared escitalopram with a variety of other antidepressants, including citalopram and venlafaxine, and suggest that escitalopram may have modest superiority in the treatment of individuals with severe depression. However, a clinically significant superiority of escitalopram over citalopram or other antidepressants in the "real world" of psychiatric practice is not established.

CHAPTER 15

Trazodone and Nefazodone

Robert N. Golden, M.D.
Karon Dawkins, M.D.
Linda Nicholas, M.D.

Trazodone was among the earliest "second-generation" antidepressants to become available for clinical use in the United States in the early 1980s. Its side-effect profile and potential toxicity were considerably different from--and in many instances preferable to--those of the original tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). Several years later, trazodone's pharmacological "cousin," nefazodone, became available.

Trazodone

History and Discovery

Trazodone was first synthesized in Italy, and clinical studies began in the United States in 1978. In sharp contrast with most other antidepressants available at the time, trazodone showed minimal effects on muscarinic cholinergic receptors.

In 1982, trazodone was introduced for clinical use in the United States under the brand name Desyrel. Bioequivalent generic formulations are available for all tablet strengths. An extended-release preparation of trazodone (Oleptro) was removed from the U.S. market and is no longer available, and no liquid (solution or suspension) trazodone dosage form is currently marketed in the United States.

Structure-Activity Relations and Pharmacological Profile

Trazodone is a relatively weak selective serotonin reuptake inhibitor (SSRI); however, it is relatively *specific* for serotonin uptake inhibition, with minimal effects on norepinephrine or dopamine reuptake (Hyttel 1982) (Figure 15-1). Trazodone increases extracellular serotonin concentrations through a combination of mechanisms involving the serotonin transporter and the serotonin$_{2A/2C}$ receptors. In addition, trazodone has some serotonin receptor antagonist activity (Haria *et al.* 1994). Its active metabolite, *m*-chlorophenylpiperazine (m-CPP), is a potent direct serotonin receptor agonist. Thus, trazodone can be viewed as a mixed serotonergic agonist-antagonist, with the relative amount of m-CPP accumulation affecting the degree of predominant agonist activity. Sustained administration is associated with enhanced serotonergic neurotransmission in vivo in the rat brain (Ghanbari *et al.* 2010).

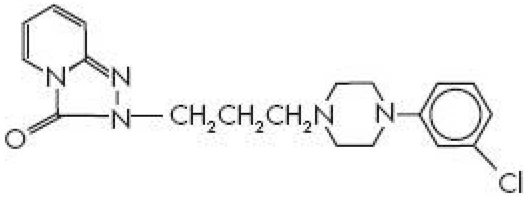

FIGURE 15-1. Chemical structure of trazodone.

In vivo, trazodone is virtually devoid of anticholinergic activity; in clinical studies, the incidence of anticholinergic side effects is similar to placebo. Trazodone is a relatively potent antagonist of postsynaptic a_1-adrenergic receptors and has a propensity to cause orthostatic hypotension. Trazodone has moderate antihistaminergic (histamine$_1$ receptor) activity.

Pharmacokinetics and Disposition

Trazodone is well absorbed after oral administration, with peak blood levels occurring about 1-2 hours after dosing. Trazodone is 89%-95% bound to plasma protein. Elimination appears to be biphasic; the initial a and subsequent b phases have half-lives of 3-6 and 5-9 hours, respectively. Bioavailability is not influenced by age or food intake.

Trazodone undergoes extensive hepatic metabolism. The active metabolite m-CPP is cleared more slowly than the parent compound (4-to 14-hour half-life) and reaches higher concentrations in the brain than in plasma (Caccia *et al.* 1981). The cytochrome P450 (CYP) 2D6 and CYP3A4 microsomal enzyme systems play a role in trazodone metabolism. The relation between steady-state trazodone blood levels and clinical response is not defined.

Mechanism of Action

The ultimate mechanism of action of trazodone remains unclear. Although the drug is described as a serotonin reuptake inhibitor, its effects on this neurotransmitter system are complex. Trazodone has relative selectivity for serotonin reuptake sites (Hyttel 1982); however, in vivo, it blocks the head twitch response induced by classic serotonin agonists in animals. The potent serotonin receptor agonist properties of trazodone's major metabolite, m-CPP, may play a role in the mechanism of action. Trazodone, unlike most antidepressants, does not produce downregulation of b-adrenergic receptors in the rat cortex (Sulser 1983).

Indications and Efficacy

The primary indication for trazodone is treatment of major depressive disorder (MDD). Early reviews found that trazodone's antidepressive efficacy was similar to that of the TCAs and the tetracyclic mianserin (Schatzberg 1987).

Questions have been raised about the effectiveness of trazodone in treating severely ill individuals with depression, especially those who have prominent psychomotor retardation. Shopsin *et al.* (1981) pointed out that in several unpublished double-blind, controlled studies, the rates of clinical response to trazodone were low (i.e., 10%-20%).

The performance of trazodone, in direct comparisons with other second-generation antidepressants, has been mixed. In a double-blind, placebo-controlled comparison with venlafaxine, response rates were 55% for placebo, 60% for trazodone, and 72% for venlafaxine. Trazodone was more effective than venlafaxine in ameliorating sleep disturbances but was associated with more dizziness and somnolence (Cunningham *et al.* 1994). In a double-blind comparison with bupropion, response rates were 46% for trazodone and 58% for bupropion (Weisler *et al.* 1994). In a double-blind study of 200 hospitalized patients experiencing a moderate to severe major depressive episode, mirtazapine yielded greater reductions in depression ratings than trazodone (van Moffaert *et al.* 1995). In a recent double-blind trial of extended-release venlafaxine versus once-a-day trazodone, both medications were effective in the treatment of MDD, with the trazodone formulation producing a statistically significant reduction in Hamilton Rating Scale for Depression scores by day 7 (Fagiolini *et al.* 2020).

Three double-blind studies reported that trazodone had antidepressant efficacy similar to that of other antidepressants in elderly patients (Gerner 1987). However, trazodone's association with orthostatic hypotension may increase the risk of falls, with devastating consequences for elderly patients. Trazodone is often helpful for geriatric patients with depression who have severe agitation and insomnia. A Cochrane Database Review found insufficient evidence to support trazodone as a treatment for the behavioral and psychological symptoms of dementia, although the review authors could not conclude that trazodone was ineffective, given the limited number of eligible studies (Martinon-Torres *et al.* 2004). In a study of 30 patients with Alzheimer's disease, trazodone normalized circadian rhythms (Grippe *et al.* 2015).

In a randomized, double-blind, placebo-controlled trial, the efficacy of trazodone was comparable to that of diazepam for generalized anxiety disorder, although diazepam treatment led to greater improvement in the first 2 weeks of treatment (Rickels *et al.* 1993).

Many clinicians use low-dosage trazodone as an alternative to benzodiazepines for the treatment of insomnia. At one point, trazodone was the second most prescribed agent for primary insomnia, even though there is minimal evidence to support its use for this indication (Mendelson 2005). In a recent meta-analysis, Yi *et al.* (2018) found trazodone to be effective in improving sleep maintenance by decreasing the number of early awakenings and enhancing perceived sleep quality, although there were no significant improvements in sleep efficiency. Yet the American Academy of Sleep Medicine clinical practice guideline does not recommend trazodone as a treatment for sleep onset or sleep maintenance insomnia (Sateia *et al.* 2017). Trazodone improved apnea-hypopnea index scores for patients with obstructive sleep apnea without any deleterious effects on oxygen saturation or non-rapid eye movement arousal threshold, suggesting that it might be beneficial in treating obstructive sleep apnea (Smales *et al.* 2015).

Trazodone is more effective than placebo when added to antipsychotic medication in the treatment of the negative symptoms of schizophrenia (Singh *et al.* 2010). A recent double-blind, placebo-controlled trial reported that trazodone was effective in treating antipsychotic-induced akathisia (Shams-Alizadeh *et al.* 2020).

Trazodone is commonly used off-label to treat a number of conditions, including bulimia nervosa, fibromyalgia, chronic pain, and diabetic neuropathy (Bossini *et al.* 2015). Adequately powered randomized controlled trials are needed to determine whether there is sufficient evidence to support trazodone's use for any of these indications.

Trazodone should be initiated at a low dosage and increased gradually, based on clinical response and tolerance to side effects. For the treatment of a major depressive episode, the suggested initial dosage is 150 mg/day, with increases of 50-mg increments every 3-4 days. Doses may be divided, but many patients prefer bedtime dosing because of the sedating effects. Although the maximum dosage recommended for outpatients is 400 mg/day, dosages up to 600 mg/day have been used for inpatients with more severe depression. When trazodone is prescribed as a hypnotic agent, the usual dose is 50 mg at bedtime, although some patients may require as little as 25 mg or as much as 200-300 mg.

Side Effects and Toxicology

Because of its lack of anticholinergic side effects, trazodone is especially useful for patients with prostatic hypertrophy, closed-angle glaucoma, or severe constipation. Trazodone's propensity to cause sedation is a double-edged sword. For many individuals, the relief from agitation, anxiety, and insomnia can be rapid; for others, including those with psychomotor retardation and low energy, trazodone may not be well tolerated.

Trazodone was among the top three medications associated with orthostatic hypotension in patients attending a Veterans Affairs geriatric clinic (Poon and Braun 2005). More than 200 cases of trazodone-associated priapism have been reported (Thompson *et al.* 1990), and the estimated incidence of abnormal erectile function is approximately 1 in 6,000 male patients. The risk appears to be greatest during the first month of treatment at low dosages (less than 150 mg/day). Early recognition of any abnormal erectile function is important and should prompt immediate discontinuation.

In overdose situations, trazodone appears to be *relatively* safer than TCAs, MAOIs, and a few of the other second-generation antidepressants, especially when it is the only agent taken. Fatalities are rare, and uneventful recoveries have been reported after ingestion of doses as high as 6,000-9,200 mg (Ayd 1984). When trazodone overdoses occur, clinicians should carefully monitor for hypotension.

Trazodone has the potential to impair driving skills, especially in new users, who have been shown to have an increased risk of motor vehicle crashes. The risk estimate for trazodone is roughly comparable to that of a blood alcohol concentration level of 0.09% (Hansen *et al.* 2015).

Drug-Drug Interactions

Trazodone can potentiate the effects of other CNS depressants. Patients should be warned about increased drowsiness and sedation when trazodone is combined with other CNS depressants, including alcohol.

The combination of trazodone with an MAOI, as with other antidepressants, should be handled with great caution, although there are case reports of successful combined use. Development of serotonin syndrome has been associated with the combination of trazodone with other pro-serotonergic agents. Trazodone inhibits the antihypertensive effects of clonidine. Trazodone can cause hypotension, especially orthostatic hypotension, and concomitant administration with antihypertensive therapy may require a reduction in the dosage of the antihypertensive agent.

Clinically significant cases of suspected trazodone-warfarin interactions have been described.

Nefazodone

History and Discovery

Trazodone's sedative properties and association with orthostatic hypotension inspired an effort to discover a modified molecule that would possess a more desirable pharmacological profile. This led to the development of nefazodone, which became available in the United States in 1994. Nefazodone and trazodone share a common active metabolite.

In 2004, the manufacturer of Serzone (nefazodone) announced that it was discontinuing the drug's sale in the United States, although generic nefazodone remains available. The drug had been banned in many countries because of its association with liver toxicity, and lawsuits against that manufacturer and the FDA were initiated in the United States.

Structure-Activity Relations and Pharmacological Profile

Nefazodone is a serotonin$_2$ (5-HT$_2$) receptor antagonist and a weak inhibitor of serotonin and norepinephrine reuptake (Figure 15-2). It has little affinity for a$_2$-adrenergic, b-adrenergic, or serotonin$_{1A}$ receptors, and its affinity for the a$_1$-adrenergic receptor is less than that of trazodone. Nefazodone is inactive at most other receptor-binding sites (Taylor *et al.* 1986).

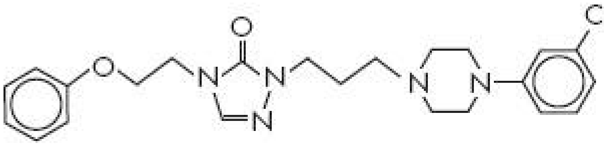

FIGURE 15-2. Chemical structure of nefazodone.

Pharmacokinetics and Disposition

Nefazodone is rapidly and completely absorbed and undergoes extensive first-pass metabolism, resulting in low (about 20%) and variable oral bioavailability. The plasma half-life is 2-4 hours. Nefazodone has three active metabolites: triazole dione, hydroxynefazodone,

and m-CPP. Triazole dione is a specific 5-HT$_2$ receptor antagonist with weaker affinity for that receptor than the parent compound and no appreciable effects on serotonin reuptake. With a plasma half-life of 18 hours, triazole dione predominates in the plasma, occurring at concentrations approaching four times those of the parent compound. Hydroxynefazodone has affinities for the 5-HT$_2$ receptor and serotonin reuptake site that are similar to those of the parent compound. Its plasma half-life is between 1.5 and 4 hours, and at steady state, plasma concentrations are approximately 40% of those of the parent compound. m-CPP is a direct agonist at the serotonin$_1$, 5-HT$_2$, and serotonin$_3$ receptors, with one-order-of-magnitude higher affinity for 5-HT$_{2C}$ receptors. m-CPP has a plasma half-life of 4-8 hours, and its plasma concentrations are only 7% of those seen with the parent compound (DeVane *et al.* 2002). However, the ratios of m-CPP to nefazodone concentrations in the brain are 47:1 and 10:1 in the mouse and rat, respectively. Brain concentrations of hydroxynefazodone in the rat are less than 10% of those in plasma, suggesting very poor blood-brain barrier penetration. Thus, despite its relatively lower plasma concentrations, m-CPP has a substantial presence in the brain, whereas the in vivo activity of hydroxynefazodone may be mostly the result of its biotransformation to m-CPP (Nacca *et al.* 1998).

Nefazodone has nonlinear kinetics, with greater than proportional mean plasma concentrations with higher dosages. Nefazodone is extensively (99%) but loosely protein bound (Teva Pharmaceuticals 2014). In patients with hepatic cirrhosis, single-dose nefazodone and hydroxynefazodone levels are about twice as high as in healthy volunteers (Barbhaiya *et al.* 1995).

Mechanism of Action

The mechanism of action of nefazodone is poorly understood. Nefazodone antagonizes 5-HT$_2$ receptors and inhibits reuptake of serotonin and norepinephrine (Teva Pharmaceuticals 2014). Several reviews refer to nefazodone as a "dual-acting" antidepressant, suggesting that it enhances both serotonergic and noradrenergic neurotransmission via uptake blockade. Although nefazodone has similar effects on the serotonin and norepinephrine transporters, this observation is potentially misleading. Nefazodone's inhibition of norepinephrine reuptake is weaker than that of the SSRI fluoxetine and is approximately three orders of magnitude weaker than what is seen with conventional norepinephrine reuptake inhibitors. Furthermore, nefazodone's inhibition of serotonin reuptake is nearly identical to that of desipramine and more than 100-fold less than that of fluoxetine (Bolden-Watson and Richelson 1993). Thus, the dual action of nefazodone refers to minimal, albeit equal, effects on serotonin and norepinephrine reuptake inhibition.

In humans, therapeutic dosages of nefazodone do not cause sustained serotonin uptake inhibition at the platelet serotonin transporter (Narayan *et al.* 1998). The active metabolite m-CCP, which appears to predominate in the brain because of greater penetration of the blood-brain barrier (Nacca *et al.* 1998), may play an important role in the mechanism of action.

Indications and Efficacy

In three of four Phase III imipramine-and placebo-controlled studies, nefazodone demonstrated similar efficacy to imipramine; in one of these studies, neither active drug had significantly greater efficacy than placebo (Rickels *et al.* 1995). The incidences of premature treatment discontinuation and side effects were higher for imipramine than for nefazodone (Rickels *et al.* 1995). In double-blind studies without placebo control groups, there were no significant differences between the clinical responses to nefazodone and sertraline or paroxetine in outpatients with depression (Feiger *et al.* 1996). Hospitalized patients with severe MDD had higher response rates to nefazodone compared with placebo (Feighner *et al.* 1998). In patients with moderate to severe MDD, the efficacy of amitriptyline was superior to that of nefazodone (Ansseau *et al.* 1994). Keller *et al.* (2000) compared nefazodone, cognitive-behavioral therapy (CBT), and their combination in a double-blind study of patients with chronic MDD. Each monotherapy yielded a response rate of 48%, whereas the combined treatment had greater efficacy (73%). In another study, depressed patients who did not respond to 12 weeks of treatment with either nefazodone or CBT achieved significant improvement when they were switched to the other treatment (Schatzberg *et al.* 2005). Nefazodone has demonstrated effectiveness in the continuation phase of treatment in double-blind studies (Baldwin *et al.* 2001).

In a double-blind, placebo-controlled study, nefazodone was safe and effective in the treatment of depression for patients with alcohol dependence, although it did not add any advantage over a psychoeducational group intervention in terms of drinking outcomes (Roy-Byrne *et al.* 2000). A double-blind controlled study reported that nefazodone was not efficacious for the treatment of alcohol dependence (Kranzler *et al.* 2000). A randomized, placebo-controlled, double-blind multicenter study compared nefazodone versus placebo and CBT versus nondirective group counseling (GC) for relapse prevention in alcohol dependence. Male patients (*n* = 242) received 1) nefazodone plus GC, 2) nefazodone plus CBT, 3) placebo plus GC, or 4) placebo plus CBT. There were no differences among the four groups in cumulative days of abstinence or amount of alcohol consumed during the initial 12-week study phase. After 1 year, the only significant difference among the groups was higher alcohol consumption in the nefazodone plus GC group, raising concerns that nefazodone may potentially increase the risk of relapse

(Wetzel *et al.* 2004). Other potential clinical applications for nefazodone have been explored, including treatment of PTSD (Jeffreys *et al.* 2012).

The usual starting dosage of nefazodone is 200 mg/day in two divided doses. The suggested dosage range is 300-600 mg/day. Increases should be in increments of 100-200 mg/day at weekly intervals. The starting dosage for elderly or debilitated patients should be lowered to 100 mg/day taken in two divided doses, and the rate of titration should be adjusted accordingly (Teva Pharmaceuticals 2014). Zajecka *et al.* (2002) reported that in studies comparing low-dosage (50-250 mg/day) and high-dosage (100-500 mg/day) nefazodone, better clinical response was obtained in the latter group, and the mean effective dosage ranged from 375 to 460 mg/day. A lower starting dosage should be considered when switching to nefazodone from an SSRI if a full washout has not been completed. Once-daily bedtime dosing appears to be well tolerated and effective.

Side Effects and Toxicology

In initial clinical trials that included approximately 2,250 patients, side effects more frequently associated with nefazodone than with placebo included dizziness, asthenia, dry mouth, nausea, and constipation (Fontaine 1993).

There are well-publicized concerns regarding the association of nefazodone with liver toxicity and liver failure, including fatalities (Voican *et al.* 2014). In 2001, the manufacturer added a black box warning to the nefazodone package insert, describing a reported rate of life-threatening liver failure in the United States of 1 case per 250,000-300,000 patient-years of nefazodone treatment. In 2004, Serzone was withdrawn from the U.S. market following its withdrawal from several international markets. The generic drug remains available in the United States.

Nefazodone appears to have advantages over SSRIs in terms of treatment-associated sexual dysfunction (Clayton *et al.* 2014). In a review of 1,338 individuals who experienced nefazodone overdoses, there were no reported deaths. The most common serious clinical effect was hypotension, reported in 1.6% of cases (Benson *et al.* 2000).

Drug-Drug Interactions

Increases in the plasma concentration of digoxin occur with concurrent nefazodone administration. Nefazodone increases the plasma concentrations of terfenadine and loratadine (with associated corrected QT prolongation), carbamazepine, and cyclosporine.

Conclusion

Trazodone was one of the earliest second-generation antidepressants. Its lack of anticholinergic effects provided an advantage over the TCAs for many patients. Its sedative properties are helpful for some patients but problematic for others. Orthostatic hypotension is a concern for elderly patients. Nefazodone and trazodone share an active metabolite, m-CPP, that may play an important role in their mechanism of action. The risk of serious liver damage led to the removal of Serzone from the market in several countries, although generic nefazodone is currently available in the United States.

CHAPTER 16

Vortioxetine

Charles-Yoland Desfosses, M.D.
Pierre Blier, M.D., Ph.D.

History and Discovery

Vortioxetine, formerly denoted Lu AA21004, was produced by Lundbeck in an attempt to add to a selective serotonin reuptake inhibitor (SSRI) additional properties, namely, serotonin (5-hydroxytryptamine [5-HT]) type 1A (5-HT_{1A}) and type 3 (5-HT_3) receptor affinities (Bang-Andersen *et al.* 2011). This was based on the premises that the antidepressant effect of SSRIs can be enhanced by combining them with a 5-HT_{1A} agonist and that 5-HT_3 antagonists are antiemetic drugs, with nausea being a common side effect of SSRIs (Sanchez *et al.* 2015). Eleven placebo-controlled studies for major depressive disorder (MDD) were conducted using a dosage ranging from 1 mg/day to 20 mg/day (Table 16-1); five of these studies included an active comparator group (venlafaxine in one study and duloxetine in the other four) (Sanchez *et al.* 2015). Vortioxetine was first approved in the United States and in Europe in 2013 for the treatment of MDD. Initially marketed under the brand name Brintellix, the drug was subsequently renamed Trintellix to avoid confusion with the anticoagulant Brilinta. No generic equivalent products are yet available, given that regulatory approval occurred relatively recently (Rudge 2021).

Structure-Activity Relations

Vortioxetine is a piperazine derivative, and its chemical name is 1-[2-(2,4-dimethylphenylsulfanyl)-phenyl]-piperazine (Figure 16-1).

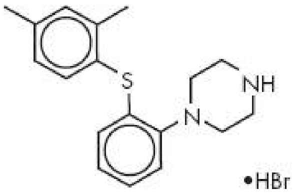

FIGURE 16-1. Chemical structure of vortioxetine.

The medication is produced in the form of a hydrobromide (HBr) salt.

Pharmacological Profile

Vortioxetine is described as a multimodal 5-HT agent because it acts on two types of neuronal elements: the 5-HT transporter and several 5-HT receptor subtypes. Among monoamine transporters, it binds selectively to the 5-HT transporter, but only to the same extent as other SSRIs at its maximal recommended regimen, as shown in PET studies in humans (Areberg *et al.* 2012; Meyer *et al.* 2004; Stenkrona *et al.* 2013). In order of affinity for human receptors, vortioxetine is a 5-HT transporter inhibitor, a 5-HT_3 antagonist, a full 5-HT_{1A} agonist, a 5-HT_7 antagonist, a partial 5-HT_{1B} agonist, and a 5-HT_{1D} antagonist (Mork *et al.* 2012). On the basis of plasma levels and affinity values, all of these targets could be engaged by vortioxetine to physiologically relevant levels within its usual therapeutic dosage range. Although the clinical significance of these various activities at 5-HT receptors in the presence of lower occupation of 5-HT transporters has not been determined, synergies between such neuronal elements on neurotransmitter levels have been documented in the brains of laboratory animals (Sanchez *et al.* 2015).

Pharmacokinetics and Disposition

The pharmacokinetics of vortioxetine are linear and dose proportional across a wide dosage range (2.5 mg-60 mg) when administered once daily. Vortioxetine is well absorbed (approximately 75%) from the gastrointestinal tract, and because its bioavailability is similar under fasting and fed conditions, it may be taken without regard to meals. It reaches a plasma peak in 7-11 hours, and it is 98% bound to plasma proteins. Vortioxetine is not a substrate for the permeability glycoproteins, which indicates that its brain levels will not be affected by possible polymorphisms of these efflux carriers. The terminal half-life of vortioxetine is about 66 hours, and steady-state concentrations are achieved after 2 weeks; consequently, complete elimination requires 2 weeks as well (Areberg *et al.* 2014; Bundgaard *et al.* 2016).

Metabolism

Vortioxetine is metabolized extensively through oxidation and subsequently by glucuronic conjugation. The cytochrome P450 (CYP) 2D6 isoenzyme is the main enzyme catalyzing its catabolism to its major carboxylic acid metabolite, which is pharmacologically inactive. About two-thirds of the inactive metabolites are excreted in the urine and the last third in the feces. Very small amounts of unchanged vortioxetine are excreted in the urine. No dosage adjustment is necessary in patients with renal impairment or mild to moderate hepatic impairment; however, vortioxetine is not recommended in patients with severe hepatic insufficiency. Plasma levels of vortioxetine are about 2 times higher in poor metabolizers of CYP2D6 and when it is administered with bupropion (Areberg *et al.* 2014; Chen *et al.* 2013).

Indication and Efficacy

The clinical development program for vortioxetine in MDD has been successful, and currently the only approved indication of vortioxetine worldwide is for the treatment of MDD.

To this day, 8 of 14 placebo-controlled short-term studies using change in the Montgomery-Asberg Depression Rating Scale (MADRS; Montgomery and Asberg 1979) as the primary endpoint have been positive (Alvarez *et al.* 2012; Baldwin *et al.* 2012a; Boulenger *et al.* 2014; Henigsberg *et al.* 2012; Inoue *et al.* 2018, 2020; Jacobsen *et al.* 2015; Jain *et al.* 2013; Mahableshwarkar *et al.* 2013, 2015a, 2015b; Nishimura *et al.* 2018; Wang *et al.* 2019), including one in elderly patients (Katona *et al.* 2012). There is also one double-blind maintenance study with a duration of 24 weeks that was positive (Boulenger *et al.* 2012), and there are five open-label studies over 52 weeks that assessed vortioxetine's safety, tolerability, and maintained effectiveness in patients with MDD treated with 5-10 mg/day (n = 1,313) or 15-20 mg/day (n = 1,144; Baldwin *et al.* 2016; Vieta *et al.* 2017).

Of the short-term studies, seven were active referenced (six duloxetine, one venlafaxine XR) (Borhannejad *et al.* 2020; Boulenger *et al.* 2012; Inoue *et al.* 2020; Koesters *et al.* 2017; Wang *et al.* 2019). Only one double-blind study examined the responsiveness to vortioxetine in 493 patients with MDD who had not responded adequately to an SSRI or a serotonin-norepinephrine reuptake inhibitor (SNRI) (Montgomery *et al.* 2014). In this study, patients were asked to decrease their current drug regimen to the minimal effective dosage in the week prior to their random assignment to either vortioxetine or the melatonin receptor agonist/5-HT$_{2B/2C}$ antagonist agomelatine. Both agents could be titrated to their maximal recommended doses. Vortioxetine was statistically superior to agomelatine.

Only two other studies have directly compared vortioxetine to another medication (sertraline and venlafaxine). In both cases, vortioxetine was not inferior to its comparator (Borhannejad *et al.* 2020; Wang *et al.* 2015).

A recent meta-analysis found 17 studies that used the MADRS as a primary or secondary endpoint with a total of 7,269 patients randomly assigned to either vortioxetine (3,630) or placebo (3,639) (Iovieno *et al.* 2021). This study found an overall standardized mean difference (SMD) of 0.33 (0.24-0.41) favoring vortioxetine, with increments in the SMD of 0.24 (0.08-0.39), 0.33 (0.19-0.47), 0.26 ([?]0.06 to 0.58), and 0.44 (0.27-0.62) for dosages of 5, 10, 15, and 20 mg/day, respectively. It is noteworthy that only three studies used the 15 mg/day dosage, which could account for the lack of statistical significance for this dosage.

A Cochrane systematic review and meta-analysis also concluded that vortioxetine may be more effective than placebo for response (Mantel-Haenszel RR, 1.35; 95% CI, 1.22-1.49; 14 studies, 6,220 participants), remission (RR 1.32; 95% CI, 1.15-1.53; 14 studies, 6,220 participants), and depressive symptoms (measured using the MADRS; mean deviation [MD], [?]2.94, 95% CI, [?]4.07 to [?]1.80; 14 studies, 5,566 participants [Koesters *et al.* 2017]).

On the basis of such results, the recommended effective dosage ranges from 5 mg/day to 20 mg/day. In adults ages 18-65 years, the usual recommended starting dosage is 10 mg/day; for convenience, vortioxetine is usually taken in the morning after a meal, but it can also be taken at night. In elderly patients, the starting dosage should be 5 mg/day. Although in controlled studies the dosage was commonly increased after 1 week, in clinical practice uptitration should occur after a minimum of 2 weeks, given that this is the time necessary to achieve a plasma steady-state level.

There have been four short-term placebo-controlled studies in generalized anxiety disorder (Bidzan *et al.* 2012; Mahableshwarkar *et al.* 2014a, 2014b; Rothschild *et al.* 2012) and one large relapse prevention trial (Baldwin *et al.* 2012b). Of these studies, one short-term trial (Bidzan *et al.* 2012) and the relapse prevention trial were positive (Baldwin *et al.* 2012b). However, in meta-analyses, vortioxetine did not separate from placebo for dosages of 2.5, 5, or 10 mg/day (Qin *et al.* 2019). Studies of higher dosages (i.e., 15 mg/day or 20 mg/day) would be interesting, as anxiety disorders generally respond to higher doses than depressive disorders. Although methodological issues may have been at play in the failed trials, there is not yet enough evidence to proceed with an indication of vortioxetine in generalized anxiety disorder.

On the basis of the premise that the pharmacological profile of vortioxetine could have beneficial effects on cognitive dysfunction in MDD, cognitive testing was included in many trials, either as the primary endpoint or as part of the secondary endpoints. The Digit Symbol Substitution Test (DSST; a pencil-and-paper task that assesses attention, speed of processing, and executive function) was most often used. Other cognitive tests used in trials of vortioxetine include the Rey Auditory Verbal Learning Test and the University of California

San Diego Performance-based Skills Assessment (UPSA). It is interesting that a functional MRI study found evidence supporting a direct effect of vortioxetine on neural circuitry in patients with remitted depression (Smith *et al.* 2018).

Initially three short-term trials examined cognitive function with a battery of tests, one in elderly patients and two with a primary outcome measure of improvement in cognitive function, and all three trials yielded positive antidepressant action over placebo (Katona *et al.* 2012; Mahableshwarkar *et al.* 2015c; McIntyre *et al.* 2014). Vortioxetine exerted a significantly greater effect over placebo on performance on the DSST in all three studies. In contrast, there was no significant effect of duloxetine (60 mg/day) over placebo on performance on the DSST in the two studies that used this medication as a comparator (Katona *et al.* 2012; Mahableshwarkar *et al.* 2015c). Furthermore, this beneficial action was deemed through path analysis to mostly be a direct effect independent of the antidepressant effect of vortioxetine. The effect of vortioxetine on cognition found in these three studies was confirmed in a random effects meta-analysis (McIntyre *et al.* 2016) as well as in a network meta-analysis, in which it was shown to be the only medication with antidepressant action to improve cognitive function scores on the DSST over placebo (Baune *et al.* 2018a). In more routine daily task testing (through the UPSA), vortioxetine but not duloxetine separated from placebo, with the difference being almost entirely attributable to a direct effect. These different findings led the European Medicines Agency, but not the U.S. FDA, to put in the label for vortioxetine a cognition claim for patients with MDD.

Since 2016, three other studies have used the DSST as a primary efficacy endpoint, but none showed a statistically significant difference from placebo or comparator, although all three supported vortioxetine as effective for the treatment of depression. Each of these studies had a specific focus and small sample size and thus lacked power. The first compared switching to vortioxetine or escitalopram in patients with inadequate response to their current antidepressant monotherapy (Vieta *et al.* 2018). The second studied the effects of adding vortioxetine versus placebo to the current treatment for patients in full or partial remission with residual cognitive symptoms (Nierenberg *et al.* 2019). The third compared vortioxetine to paroxetine or placebo in working patients with depression (Baune *et al.* 2018b).

Apart from the above studies in which improvement in cognitive function was the primary outcome measure, many other studies have investigated the cognitive effects of vortioxetine through secondary endpoints or post hoc analysis of patient populations of studies that had included various scales of cognitive, social, or workplace functioning with mixed but primarily positive results (Christensen *et al.* 2018; Harrison *et al.* 2016; Inoue *et al.* 2020; Jacobson *et al.* 2020; Keefe *et al.* 2018; Lee *et al.* 2018; McIntyre *et al.* 2017).

An interventional 52-week open-label study, AtWoRC (Assessment in Work productivity and the Relationship with Cognitive symptoms; Chokka *et al.* 2019), investigated the association between cognitive symptoms and workplace productivity in working patients with depression treated with vortioxetine (10-20 mg/day). This study found a significant correlation between the 20-item Perceived Deficits Questionnaire--Depression and the Work Limitations Questionnaire at both week 12 and week 52.

In recent years, studies have investigated vortioxetine in patients with other diagnoses. An open-label, flexible-dose study showed statistically significant improvement for panic disorder (Shah and Northcutt 2018). A randomized double-blind, placebo-controlled trial showed statistically significant improvement in negative symptoms of patients with chronic schizophrenia when vortioxetine was used in addition to risperidone 4-6 mg/day (Moazen-Zadeh *et al.* 2020). Also, vortioxetine significantly improved quality of life compared with placebo in a double-blind randomized controlled trial for patients with irritable bowel syndrome (Seddighnia *et al.* 2020). No statistically significant difference was found versus placebo for social anxiety disorder comorbid with depression (although there was a significant effect on the MADRS [Liebowitz *et al.* 2017]), ADHD (Biederman *et al.* 2019), binge-eating disorder (Grant *et al.* 2019), or PTSD (Dunlop *et al.* 2021).

Two studies investigated the effects of vortioxetine on cognition in patients with cognitive decline. One open-label observational 12-month study compared the effects of vortioxetine versus other medications with antidepressant properties (control group) on performance on the Mini-Mental State Examination (primary endpoint) and other cognitive tests among patients with mild Alzheimer's disease and depressive symptoms. This study showed that vortioxetine produced statistically significant improvement on the Mini-Mental State Examination and most cognitive tests, as well as on Hamilton Rating Scale for Depression scores and Cornell Scale for Depression in Dementia total scores (Cumbo *et al.* 2019). The other study evaluated the effects of adding vortioxetine versus placebo to a 26-week course of cognitive training for adults age 65 years and older with age-related cognitive decline. The primary outcome was global cognitive performance (using the National Institutes of Health Toolbox Cognition Battery

fluid cognition composite), on which vortioxetine separated from placebo only at the 12-week time point (Lenze *et al.* 2020).

Side Effects and Toxicology

The most common adverse reactions reported with vortioxetine use are nausea, constipation, and vomiting (Takeda Pharmaceuticals 2021). The main side effect of vortioxetine on treatment initiation is nausea. It occurs at about the same rate as with SSRIs and SNRIs, generally in about one-quarter to one-third of patients (Citrome 2014). This finding is somewhat surprising, as vortioxetine is a potent 5-HT$_3$ receptor antagonist, which should prevent any nausea resulting from 5-HT reuptake inhibition. However, nausea can be produced by a variety of mechanisms, such as opioid and dopamine receptor activation, b-human chorionic gonadotropin hormone, and, importantly, 5-HT$_{1A}$ receptor agonism (as with the 5-HT$_{1A}$ receptor agonist buspirone). The latter effect is likely responsible for the transient nausea often reported during the first 2 weeks of vortioxetine administration, given the potent 5-HT$_{1A}$ receptor agonism of vortioxetine. In an analysis of data from randomized placebo-controlled trials and open-label extension studies by Baldwin *et al.* (2016), this side effect was found to lead to discontinuation of treatment in 1%-4% of subjects and appeared to be dose dependent. Apart from these gastrointestinal side effects, other side effects reported in the vortioxetine group were generally not markedly different from those reported in the placebo group (Baldwin *et al.* 2016). Overall, discontinuation due to treatment-emergent adverse events was dose dependent and was between 4.5% and 8.5%, reaching the same level as with 60 mg/day of duloxetine, with the placebo rate being 3.5% (Baldwin *et al.* 2016). In a study comparing the treatment initiation of oral vortioxetine (10 mg/day) with an initial dose of intravenous vortioxetine versus intravenous placebo (Vieta *et al.* 2019), nausea was also the most common side effect, reported by 48% of the intravenous vortioxetine group versus 32% of the intravenous placebo group, with comparable severity between the two groups. In the intravenous vortioxetine group, nausea appeared within the first 2 days, with no new incidence after 2 days; the mean duration was 4.5 days, much shorter than the mean duration of 12.5 days in the placebo group (Vieta *et al.* 2019). When side effects are problematic, vortioxetine should be withheld for 3 days (given its long half-life) and restarted at half the prior daily dose.

Vortioxetine has not exerted clinically meaningful effects on body weight in short-term or long-term clinical studies. It has not been associated with an incidence of insomnia or daytime somnolence that is above the placebo level, unlike venlafaxine, which produces greater rates of insomnia, or duloxetine, which produces greater rates of somnolence. There are no significant discontinuation symptoms associated with abrupt cessation of vortioxetine, as is expected from its long terminal half-life.

Sexual dysfunction is a class side effect of drugs that potently inhibit the 5-HT transporter. Rates of sexual dysfunction (as measured on the Arizona Sexual Experiences Scale) among patients receiving vortioxetine 5 mg/day or 10 mg/day did not differ from rates for patients receiving placebo; however, for patients receiving vortioxetine 20 mg/day, rates of sexual dysfunction were equivalent to rates for patients receiving duloxetine 60 mg/day (Baldwin *et al.* 2016). These results are consistent with the lower occupation of the 5-HT transporter with vortioxetine at dosages lower than at 20 mg/day, which is about the same as with duloxetine 60 mg/day (i.e., 80% [Takano *et al.* 2006]). In one study, 477 patients with MDD who were responding to paroxetine, sertraline, or citalopram but experiencing treatment-emergent sexual dysfunction were switched to either vortioxetine or escitalopram (10 mg/day or 20 mg/day [Jacobsen *et al.* 2015]). Benefits of vortioxetine over escitalopram were significantly greater on four of five dimensions of the Changes in Sexual Functioning Questionnaire--Short Form and for all three phases of sexual functioning. Although the absolute difference between the two groups was significant, it is important to note that three-quarters of patients on vortioxetine were taking 20 mg/day.

No cases of vortioxetine overdose are reported in the literature. A supratherapeutic dosage of vortioxetine 40 mg/day for 14 days did not produce clinically relevant electrocardiography or hemodynamic changes (i.e., QTc prolongation of 5 ms [Wang *et al.* 2013]).

Drug-Drug Interactions

Vortioxetine must never be administered in combination with a monoamine oxidase inhibitor (MAOI). Before vortioxetine is started, there must be an elimination period of 14 days for an irreversible MAOI but only 2 days in the case of the reversible MAOI moclobemide. Similarly, there must be a 14-day elimination period of vortioxetine before either an irreversible MAOI or moclobemide is initiated.

Vortioxetine is not an inhibitor or an inducer of any metabolic enzymes. Consequently, it will not alter levels of other medications through metabolic interference. Complete inhibitors of CYP2D6, such as fluoxetine and paroxetine, as well as moderate inhibitors, such as bupropion and duloxetine, will approximately double the exposure (area under the curve) to vortioxetine. These interactions are expected to occur mainly in switch situations, which are discussed below. In such concomitant regimens, the dosage of vortioxetine should be reduced by half (D'Empaire *et al.* 2011; Hvenegaard *et al.* 2012).

Triptans for the treatment of migraines may be less effective in the presence of vortioxetine. This class of agents acts mainly by activating 5-HT$_{1D}$ receptors, whereas vortioxetine is a 5-HT$_{1D}$ receptor antagonist. However, because the affinity of vortioxetine for the 5-HT$_{1D}$ receptor is the lowest among all of the 5-HT neuronal elements (Mork *et al.* 2012), the activity of triptans may not be reduced at lower dosages of vortioxetine.

Strategies for Switching to Vortioxetine

Despite an extensive clinical program, there are actually only three studies that have reported on a switch to vortioxetine from other medications with antidepressant effects (Jacobsen *et al.* 2015; Mills *et al.* 2021; Montgomery *et al.* 2014). Although these patients seemed to tolerate the switch to vortioxetine well, in clinical practice switching has been more problematic. A likely explanation for patients prematurely stopping vortioxetine may stem more from the abrupt, or too rapid, interruption of the SSRI or SNRI than from vortioxetine itself. As illustrated in Figure 16-2, SSRIs or SNRIs are eliminated within

several days, which rapidly decreases the occupation of the 5-HT transporters, although a steady-state of vortioxetine is achieved only after 2 weeks, then producing about 60% occupancy at 10 mg/day and 80% at 20 mg/day. Consequently, discontinuation symptoms could occur during a rapid switch that could be exacerbated by the potent 5-HT$_{1A}$ agonistic profile of vortioxetine. It is thus recommended that a gradual crossover strategy be implemented when switching from SSRIs or SNRIs to vortioxetine. One exception would be a switch from fluoxetine because of its long half-life. However, because fluoxetine is a CYP2D6 inhibitor, the initial dosage of vortioxetine should be 5 mg/day, and the dosage should be gradually increased with the slow elimination of fluoxetine.

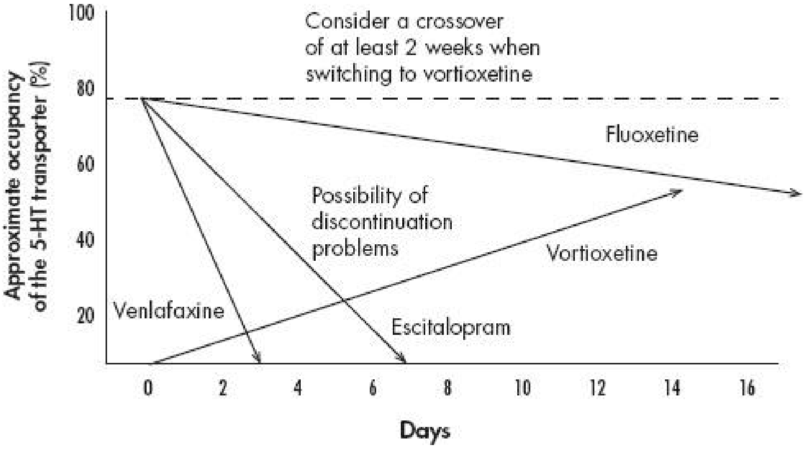

FIGURE 16-2. Relationship between serotonin transporter occupancy by various drugs used to treat depression and time following their discontinuation and the introduction of vortioxetine.

The *lines* represent the decrease in serotonin (5-HT) transporter occupancy following an abrupt cessation of the selective serotonin reuptake inhibitors escitalopram and fluoxetine and the serotonin-norepinephrine reuptake inhibitor venlafaxine (at their minimal effective doses) in comparison to the increase in 5-HT transporter occupancy following initiation of the multimodal agent vortioxetine at dosages of 5-10 mg/day. When most 5-HT reuptake inhibitors, with the exception of fluoxetine, are discontinued abruptly, discontinuation phenomena may be triggered, leading to an apparent intolerance of vortioxetine. Therefore, the ongoing medication should be decreased gradually while vortioxetine levels are building up.

Conclusion

Vortioxetine is a multimodal serotonergic agent that inhibits the 5-HT transporter, albeit to a lesser extent than other SSRIs, and has a variety of actions at five 5-HT receptor subtypes. Its only approved indication is for the treatment of MDD. Although it may produce as much mild to moderate nausea as SSRIs on treatment initiation, nausea is generally transient and seldom leads to discontinuation of treatment. At dosages of 10 mg/day or less, vortioxetine is expected to produce less sexual dysfunction than SSRIs and SNRIs. Vortioxetine does not impact the cardiovascular system, even at twice its maximal recommended dosage. Vortioxetine will not alter levels of other medications because it is not a hepatic enzyme inducer or inhibitor. It is still too early to determine its role in treatment-resistant depression. However, vortioxetine may exert a beneficial action on cognitive functioning in some patients with MDD.

CHAPTER 17

Mirtazapine

Alan F. Schatzberg, M.D.

History and Discovery

Mirtazapine, originally known as ORG 3770, was first synthesized in the Netherlands by the Department of Medicinal Chemistry of NV Organon (Kaspersen *et al.* 1989). First approved for use in major depressive disorder (MDD) in the Netherlands in 1994, mirtazapine was introduced in the United States in 1996.

Structure-Activity Relations

Mirtazapine (Figure 17-1) is a member of the piperazinoazepines, a class of chemical compounds that is unrelated to any other medication class used in the treatment of psychiatric conditions (Maris *et al.* 1999). Mirtazapine is also known by its chemical name, 1,2,3,4,10,14b-hexahydro-2-methylpyrazino[2,1-a]pyrido[2,3-c] benzazepine (Dahl *et al.* 1997; Dodd *et al.* 2000).

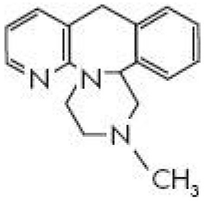

FIGURE 17-1. Chemical structure of mirtazapine.

Pharmacological Profile

Mirtazapine is described as a noradrenergic and specific serotonergic antidepressant (Holm and Markham 1999; Kent 2000; Nutt 1998). It is a potent serotonin$_2$ (5-HT$_2$), serotonin$_3$ (5-HT$_3$), and central a$_2$-adrenergic receptor antagonist (de Boer 1996; de Boer *et al.* 1995; Kooyman *et al.* 1994). Antagonism of 5-HT$_2$ and 5-HT$_3$ receptors results in an increase in serotonin$_{1A}$ (5-HT$_{1A}$) receptor-mediated transmission, thus exerting a more specific effect on serotonergic transmission, relative to the selective serotonin reuptake inhibitor (SSRI) class of antidepressants (Bengtsson *et al.* 2000; Berendsen and Broekkamp 1997; Kent 2000). In addition, because a$_2$-adrenergic receptors normally act to inhibit transmission at serotonergic and noradrenergic axon terminals, mirtazapine acts to increase the release of both serotonin (5-HT) and norepinephrine via blockade of central a$_2$ receptors (Numazawa *et al.* 1995).

Mirtazapine has no significant affinity for dopamine receptors, low affinity for muscarinic cholinergic receptors (de Boer 1996), and high affinity for histamine$_1$ receptors (de Boer 1996). Mirtazapine appears to have no effect on 5-HT and dopamine reuptake and only a minimal effect on norepinephrine reuptake (de Boer 1996; Kent 2000). The drug appears to significantly reduce cortisol levels (Laakmann *et al.* 2004; Schmid *et al.* 2006), an effect that has been demonstrated in both patients and healthy volunteers (Laakmann *et al.* 1999, 2003).

Pharmacokinetics and Disposition

Absorption

Mirtazapine is well absorbed from the gastrointestinal tract, and bioavailability does not appear to be affected by the presence of food in the stomach (Fawcett and Barkin 1998b). An oral rapidly disintegrating tablet has been available since 2001 (Benkert *et al.* 2006), along with immediate-release oral tablets. Generic equivalents are available for both dosage forms.

Distribution

Mirtazapine appears to be 85% bound to plasma proteins (Fawcett and Barkin 1998b).

Metabolism

Mirtazapine is primarily metabolized by the liver via demethylation and hydroxylation, followed by glucuronidation (Fawcett and Barkin 1998b; Merck and Co. 2020). A major metabolite, desmethylmirtazapine, and some minor metabolites are weakly active but are present in lower serum concentrations than the parent compound (Fawcett and Barkin 1998b; Kent 2000; Merck and Co. 2020). Mirtazapine lacks both autoinduction and autoinhibition of hepatic cytochrome P450 (CYP) enzymes (Fawcett and Barkin 1998b). Although in vitro studies do not demonstrate an inhibitory effect, mirtazapine is a substrate for CYP1A2, CYP2D6, and CYP3A4 (Fawcett and Barkin 1998b; Merck and Co. 2020). Mirtazapine is a mild competitive inhibitor of CYP2D6 (Barkin *et al.* 2000; Fawcett and Barkin 1998b). A pharmacogenetic study of CYP2D6 in older patients with depression did not show increased dropout rates for slow and intermediate metabolizers due to side effects of the drug (Murphy *et al.* 2003b). These findings suggest that mirtazapine is well tolerated in individuals who are slow metabolizers of CYP2D6.

Elimination

Mirtazapine and its metabolites are eliminated primarily in the urine (up to 75%) and feces (up to 15%; Fawcett and Barkin 1998b). The elimination half-life of mirtazapine is 20-40 hours (Fawcett and Barkin 1998b; Merck and Co. 2020; Stimmel *et al.* 1997). Of note, the clearance of mirtazapine may be affected by hepatic or renal impairment (Fawcett and Barkin 1998b). The elimination half-life may increase by 30%-40% in patients with hepatic impairment (Fawcett and Barkin 1998b; Kent 2000). In patients with moderate to severe renal impairment, the clearance of mirtazapine may be reduced by 30%-50% (Fawcett and Barkin 1998b; Kent 2000; Merck and Co. 2020). Although no dosage adjustments are recommended in the product labeling to compensate for renal or hepatic impairment, caution is advised.

Indications and Efficacy

Major Depressive Disorder

In a randomized, double-blind, placebo-controlled study of 90 outpatients with a major depressive episode, mirtazapine treatment resulted in clinically significant reductions in Hamilton Rating Scale for Depression (Ham-D) scores by study endpoint at 6 weeks, although improvement was noted as early as the first week (Claghorn and Lesem 1995).

A meta-analysis of four randomized, double-blind 6-week studies demonstrated that mirtazapine was as effective as amitriptyline in the treatment of MDD but had significantly fewer adverse anticholinergic, serotonergic, and cardiovascular effects (Stahl *et al.* 1997).

Pooled data from the 6-week U.S. clinical trials that were part of the new drug application showed that approximately 50% of mirtazapine-treated patients and 20% of placebo-treated patients achieved at least a 50% improvement in scores on the Ham-D (Fawcett and Barkin 1998b).

In a randomized, double-blind multicenter study comparing mirtazapine and fluoxetine, both medications were found to be well tolerated in the treatment of MDD, although mirtazapine was noted to demonstrate a significantly greater improvement in Ham-D scores beginning in the third week of treatment (Wheatley *et al.* 1998).

When mirtazapine was compared with paroxetine in a randomized, double-blind study of 275 patients with MDD, the two drugs were found to be equally well tolerated and efficacious overall, but mirtazapine-treated patients had significantly lower Ham-D and Hamilton Anxiety Scale scores at week 1, which possibly suggests a faster onset of therapeutic benefit from mirtazapine (Benkert *et al.* 2000).

Similarly, when compared with citalopram in an 8-week randomized, double-blind multicenter study of 270 patients with MDD, mirtazapine was equally well tolerated and efficacious at study endpoint but was significantly more effective (as assessed by the Hamilton Anxiety Scale, Montgomery-Asberg Depression Rating Scale, and Clinical Global Impression [CGI] Scale scores) at week 2 (Leinonen *et al.* 1999).

It is interesting that in an 8-week randomized, double-blind multicenter study comparing two antidepressants with both serotonergic and noradrenergic activity, mirtazapine was found to be equal in efficacy to venlafaxine in the treatment of MDD

with melancholic features, although it demonstrated a trend (not statistically significant) toward a higher percentage of responders and remitters (Guelfi *et al.* 2001).

In a meta-analysis of 15 studies comparing mirtazapine with an SSRI, Thase *et al.* (2010) concluded that mirtazapine was significantly more likely than the SSRI to induce remission at weeks 1, 2, 4, and 6. At week 2, the remission rates with mirtazapine were more than 70% higher than those with the SSRI, which suggests more rapid effects. A more recent systematic review of a Cochrane database showed that the optimal dosage of mirtazapine appears to be 30 mg/day or less (Furukawa *et al.* 2019).

A study that investigated several combinations of antidepressants versus monotherapy found that mirtazapine coadministered with fluoxetine was significantly more effective than fluoxetine alone. Similarly high rates of remission were observed for mirtazapine coadministered with bupropion and mirtazapine coadministered with venlafaxine (Blier *et al.* 2010).

In contrast to the findings of the Blier *et al.* (2010) study, the National Institute of Mental Health-funded Combining Medications to Enhance Depression Outcomes (CO-MED) study--in which remission and response rates for two antidepressant combinations (escitalopram plus bupropion sustained release and venlafaxine plus mirtazapine) administered from treatment initiation were compared with those for antidepressant monotherapy (escitalopram plus placebo)--failed to detect differences between groups (Rush *et al.* 2011). Baseline insomnia was not a predictor of response to single versus combination antidepressants (Sung *et al.* 2015).

The sleep effects of mirtazapine in MDD were reported by Schmid *et al.* (2006). Mirtazapine improved sleep continuity by day 2 of therapy, and the effect was sustained for at least 4 weeks. At day 28, significant increases in slow-wave and low-delta sleep were also observed.

An 8-week open-label trial of mirtazapine in 22 menopausal patients receiving estrogen replacement therapy who had MDD demonstrated an almost 90% remission rate among the study completers (Joffe *et al.* 2001).

Insufficient Response to Selective Serotonin Reuptake Inhibitor Treatment (Augmentation or Substitution Therapy)

In an 8-week open-label study of 103 outpatients with DSM-IV (American Psychiatric Association 1994) MDD complicated by a lack of response to (or intolerance of) treatment with fluoxetine, paroxetine, or sertraline, approximately one-half of the outpatients demonstrated a 50% reduction in the 17-item Ham-D score when switched to treatment with mirtazapine (Fava *et al.* 2001).

In a 4-week study of patients with persistent MDD despite adequate antidepressant monotherapy, augmentation with mirtazapine resulted in a 45% remission rate compared with a 13% remission rate among patients receiving placebo (Carpenter *et al.* 2002). Of note, in this study there were no significant differences in side effects between drug and placebo (Carpenter *et al.* 2002).

In level 3 of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, mirtazapine was compared with nortriptyline in patients whose symptoms had not responded to two previous consecutive antidepressant trials (Fava *et al.* 2006). Level 1 of STAR*D used citalopram; level 2 used a switch to another drug or augmentation.

Nortriptyline produced higher remission rates than did mirtazapine (19.8% vs. 12.3%); however, the difference was not statistically significant.

Depression and Sexual Dysfunction

In an open-label study of 103 patients with depression treated with mirtazapine, 54% of patients who had reported poor or very poor sexual functioning during prior treatment with an SSRI described an improvement in sexual functioning by study endpoint (Fava *et al.* 2001).

Similarly, Gelenberg *et al.* (2000) reported that 58% of patients with prior SSRI-induced sexual dysfunction had a return of normal sexual functioning when they switched to treatment with mirtazapine.

In contrast, augmentation with mirtazapine was no more effective than placebo augmentation in reversing SSRI-associated sexual side effects in patients with fluoxetine-associated sexual dysfunction (Michelson *et al.* 2002).

Depression in Elderly Patients

In a 6-week study of 150 outpatients (ages 55-80 years) with moderate to severe depression, mirtazapine was found to be effective and well tolerated (Halikas 1995). Half of the mirtazapine-treated patients and 35% of the placebo-treated patients demonstrated at least a 50% reduction in Ham-D scores (Halikas 1995). In another study, mirtazapine was significantly more effective than paroxetine at weeks 1, 2, 3, and 6, but not at week 8, in subjects older than 65 years (Schatzberg *et al.* 2002). Differences were observed primarily on measures of anxiety and sleep. A person's status as a carrier of the allele producing the e4 type of apolipoprotein E predicted a positive response to mirtazapine (Murphy *et al.* 2003a).

The oral disintegrating tablet formulation of mirtazapine has been studied in elderly patients and appears to be well tolerated (Nelson *et al.* 2007; Varia *et al.* 2007).

Comorbid or Primary Symptoms of Anxiety

Meta-analyses of placebo-controlled studies of patients with depression and associated symptoms of anxiety have demonstrated that mirtazapine-treated patients exhibit significantly greater improvement in symptoms of anxiety compared with placebo-treated patients (Fawcett and Barkin 1998a; Nutt 1998) beginning as early as the first week of treatment (Fawcett and Barkin 1998a).

Social Anxiety Disorder

Mirtazapine was compared with placebo in a 10-week double-blind comparison study of 66 women with DSM-IV social phobia (changed in DSM-5 [American Psychiatric Association 2013] to *social anxiety disorder*). Mirtazapine appeared to separate from placebo on several primary measures of social anxiety symptoms (Muehlbacher *et al.* 2005).

Generalized Anxiety Disorder

A reanalysis of a primary care MDD randomized controlled trial indicated that comorbid generalized anxiety disorder in MDD was a predictor of a significantly greater response to mirtazapine compared with placebo (Rifkin-Zybutz *et al.* 2020).

Obsessive-Compulsive Disorder

Koran *et al.* (2005) reported on a two-phase study (a 12-week open-label phase followed by an 8-week double-blind discontinuation phase) of mirtazapine (maximum dosage 60 mg/day) in 30 patients with OCD. In the 8-week discontinuation phase, mirtazapine was significantly more effective than placebo in preventing symptom recurrence.

Mirtazapine augmentation of citalopram was assessed in 49 nondepressed patients with OCD (Pallanti *et al.* 2004). Subjects were treated with citalopram plus placebo or citalopram plus mirtazapine under single-blind conditions. Mirtazapine appeared to speed the response to citalopram but not to improve overall response.

Posttraumatic Stress Disorder

In an early 8-week open-label study of six patients with severe chronic PTSD, one-half of the mirtazapine-treated patients demonstrated at least a 50% reduction in the CGI score and significant reductions on scales of PTSD severity (Connor *et al.* 1999).

In a later 6-week double-blind comparison study, mirtazapine was compared with sertraline in Korean veterans (Chung *et al.* 2004). At study endpoint, mirtazapine was statistically significantly superior to sertraline on several measures. Efficacy was apparently maintained to 24 weeks (Kim *et al.* 2005). However, in a more recent study of PTSD among U.S. veterans, mirtazapine failed to separate from placebo (Davis *et al.* 2020).

Alcohol Use Disorder

Mirtazapine was not found to be significantly superior to placebo in reducing alcohol use in a study of men with high alcohol consumption (de Bejczy and Soderpalm 2015), although there was a suggestion that the drug might be helpful in individuals with a family history of alcohol use disorder.

Sleep Disorders

Because of its sedating properties when used to treat depression, mirtazapine has been studied in patients with breathing-related sleep disorders. In a double-blind crossover study of seven patients with obstructive sleep apnea, mirtazapine at dosages of 4.5 mg/day and 15 mg/day produced significantly greater reductions (on the order of 46%-52%) in apnea-hypopnea index scores in comparison with placebo (Carley *et al.* 2007). However, because of concerns regarding weight gain and daytime sedation, the authors concluded that mirtazapine could not at present be recommended as a primary therapy for this disorder. In contrast, Karsten *et al.* (2017) reported that mirtazapine at 7.5 mg/day was significantly more effective than placebo in treating transient insomnia.

Chronic or Recurrent Pain

A number of case reports have indicated that mirtazapine could be beneficial for treating chronic or recurrent pain (Brannon and Stone 1999;

Brannon *et al.* 2000; Kuiken *et al.* 2005; Nutt and Law 1999). In a large observational study conducted in Germany (Freynhagen *et al.* 2006) that involved 600 individuals with comorbid pain and depression treated with mirtazapine, the drug appeared to reduce pain effectively, with a relatively low-order risk of side effects (7%), at a mean dosage of 35 mg/day. The drug has been explored in fibromyalgia with inconclusive results (Ottman *et al.* 2018; Welsch *et al.* 2018).

Mirtazapine 15-30 mg/day was reported to be effective in a double-blind crossover study of 24 nondepressed patients with chronic tension headaches (Bendtsen and Jensen 2004). The area under the curve (intensity x duration) for headache was significantly lower for mirtazapine than for placebo.

Nausea

In a case series of 20 patients with breast or gynecological cancer who were treated with mirtazapine, 19 of the patients demonstrated a significant reduction in symptoms of depression, anxiety, nausea, anorexia, and insomnia. In addition, there were no adverse drug interactions with oncology treatment regimens, including chemotherapy (Thompson 2000).

A 7-week open-label crossover investigation of mirtazapine in 20 patients with cancer found significant improvements in mood, anxiety, insomnia, appetite, weight, and pain symptoms by study endpoint (Theobald *et al.* 2002).

It has been suggested that mirtazapine could prove to be a safe and effective adjunct to cancer chemotherapy because of its ability to treat nausea via a 5-HT$_3$ receptor antagonism effect; insomnia, anorexia, and weight loss via histamine$_1$ receptor antagonism; symptoms of depression via enhanced 5-HT and noradrenergic transmission by way of a$_2$, 5-HT$_2$, and 5-HT$_3$ receptor blockade; and symptoms of anxiety via 5-HT$_2$ and 5-HT$_3$ receptor antagonism (Kast 2001). A randomized, double-blind trial reported that the incidence of nausea and vomiting after spinal anesthesia with intrathecal morphine was significantly lower in orthopedic surgery patients who received preoperative mirtazapine (30 mg) than in those who received placebo (Chang *et al.* 2010).

A review of seven cases of pregnant patients with treatment-refractory hyperemesis gravidarum and symptoms of depression and anxiety concluded that treatment with mirtazapine produced resolution of symptoms without adverse effects on the newborns (Saks 2001).

Vasomotor Symptoms

Waldinger *et al.* (2000) described four cases in which women (ages 39-60 years) experienced a near-complete resolution of symptoms of hot flushes and perspiration within the first week of treatment with mirtazapine.

Respiratory Symptoms

Mirtazapine was reported to not separate from placebo in reducing breathlessness in patients with advanced lung disease (Higginson *et al.* 2020).

Pediatric Depression and Anxiety

Mirtazapine has been assessed in several trials involving children or adolescents with MDD or anxiety disorders. In one trial in 24 adolescents with MDD, patients responded well to mirtazapine, with no dropouts due to side effects (Haapasalo-Pesu *et al.* 2004). In another small open-label trial in 18 patients with DSM-IV social phobia (social anxiety disorder), mirtazapine also demonstrated efficacy (Mrakotsky *et al.* 2008). Although there was a very high dropout rate, most of the discontinuations were not due to side effects.

Pervasive Developmental Disorders

In an open-label study of the use of mirtazapine in 26 patients with DSM-IV pervasive developmental disorders, 35% of subjects demonstrated significant improvement on CGI scores with respect to symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia (Posey *et al.* 2001).

Depression in Alzheimer's Disease

Raji and Brady (2001) described three cases of patients with comorbid Alzheimer's dementia (Mini-Mental State Examination scores of 21/30, 11/30, and 18/30) and depressive symptomatology (including weight loss, insomnia, and anxiety) who were treated safely with mirtazapine. The patients demonstrated significant improvements in appetite, weight, sleep, mood, and energy level.

However, in a large-scale trial comparing sertraline (up to 150 mg/day), mirtazapine (up to 45 mg/day), and placebo in Alzheimer's disease patients with depression, there were no differences among the three groups in terms of a reduction in depressive symptoms (Banerjee *et al.* 2011). Given these negative findings regarding benefit and the heightened risk of side effects from these drugs, the authors recommended that the current practice of prescribing antidepressants in this patient population be reconsidered. A more recent approach has been to subtype the depressive symptoms in dementia, and there is a suggestion of a possible subtype that could be helped (Zuidersma *et al.* 2019).

Negative Symptoms in Schizophrenia (Add-On Therapy)

The utility of mirtazapine in the treatment of negative symptoms (i.e., blunted affect, alogia, avolition, asociality, and anhedonia) in schizophrenia has been examined in several studies. In a 6-week double-blind, randomized, placebo-controlled trial, the addition of mirtazapine to haloperidol in the treatment of schizophrenia produced statistically significant reductions in Positive and Negative Syndrome Scale scores as well as in CGI-Severity and CGI-Improvement scores (Berk *et al.* 2001). In addition, Positive and Negative Syndrome Scale negative symptom scores in this study were found to be reduced by 42% in the group of patients who received adjunctive mirtazapine compared with the group who received placebo (Berk *et al.* 2001). Furthermore, the improvement in negative symptoms was not correlated with Ham-D scores at study endpoint, which suggests that the effect of mirtazapine on diminution of negative symptoms in schizophrenia was not a result of improvement in mood symptoms (Berk *et al.* 2001).

In a subsequent study, Berk *et al.* (2009) compared mirtazapine (30 mg/day) with placebo add-on in patients with schizophrenia being treated with atypical antipsychotics. The effects of mirtazapine on negative symptoms and cognition failed to separate from those of placebo.

Several positive studies have followed the mixed findings of Berk and colleagues. Abbasi *et al.* (2010) reported that mirtazapine add-on at 30 mg/day was significantly more effective than placebo in reducing negative symptoms and total Positive and Negative Syndrome Scale scores in patients with schizophrenia being treated with risperidone. Similarly, Cho *et al.* (2011) noted that mirtazapine augmentation separated from placebo in improving negative symptoms and cognition in patients undergoing treatment with risperidone. Neuropsychological testing results likewise showed significantly greater improvement with mirtazapine. Stenberg *et al.* (2010) reported that patients who were not sufficiently improved on first-generation antipsychotics showed significantly greater improvement in cognition with add-on mirtazapine than with placebo.

A meta-analysis examining the safety and efficacy of adjunctive antidepressants for cognitive impairment in schizophrenia included four studies of mirtazapine. In this investigation, statistically significant but minimal clinical effects were noted for all drugs (Vernon *et al.* 2014).

Antipsychotic-Induced Akathisia

Poyurovsky *et al.* (2003, 2006) conducted two double-blind, placebo-controlled studies of mirtazapine treatment of antipsychotic-induced akathisia in patients with schizophrenia. In the first study (Poyurovsky *et al.* 2003), mirtazapine 15 mg/day was compared with placebo in 26 patients. The drug was significantly superior to placebo. In the second study (Poyurovsky *et al.* 2006), mirtazapine 15 mg/day was compared with propranolol 80 mg/day or placebo in 90 patients. Both drugs separated from placebo, but propranolol was associated with clinically significant bradycardia and hypotension.

Side Effects and Toxicology

In a double-blind, placebo-controlled study of outpatients with depression, the most commonly reported side effects associated with mirtazapine treatment were somnolence, increased appetite, and weight gain (Claghorn and Lesem 1995).

In a review of data from the clinical development program for mirtazapine, the only adverse effects that occurred at a higher incidence with mirtazapine versus placebo were excessive sedation, increased appetite, weight gain, and dry mouth (Montgomery 1995). The authors noted that these side effects were typically mild and transient in nature and that they diminished over time even when dosages were increased (Montgomery 1995).

Side effects typical of SSRIs, such as nausea, diarrhea, and sexual dysfunction, appear to occur less frequently in patients treated with mirtazapine (Boyarsky *et al.* 1999; Farah 1998; Montgomery 1995; Stimmel *et al.* 1997).

Mirtazapine appears to be well tolerated in elderly individuals. The side effects most commonly reported--including somnolence, increased appetite, weight gain, and dry mouth--are of the same type as those reported in younger adults (Fawcett and Barkin 1998b; Halikas 1995). In a large study of 170,000 psychiatric inpatients in German-speaking countries (Spindelegger *et al.* 2014), mirtazapine was found to be associated with significantly fewer cardiovascular adverse events compared with all other antidepressants (i.e., monoamine oxidase inhibitors, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and SSRIs).

Mirtazapine appears to have a very low propensity to cause clinically relevant laboratory abnormalities, such as transient elevations in liver enzymes (which occur in about 2% of patients) and severe neutropenia (in

0.1% [Claghorn and Lesem 1995; Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995]). Mirtazapine can significantly reduce cortisol levels in both plasma and saliva. In addition, mirtazapine use is associated with increased plasma concentrations of triglycerides and cholesterol (Laakmann *et al.* 1999, 2003; Merck and Co. 2020).

Mirtazapine appears to have no clinically significant effects on seizure threshold or on the cardiovascular system (Claghorn and Lesem 1995; Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995).

Notably, the noradrenergic effects of mirtazapine appear to be dose dependent and increase significantly at dosages > 15 mg/day. Consistent with this pattern, the sedation associated with mirtazapine's affinity for histamine$_1$ receptors and typically experienced at dosages of [?] 15 mg/day may be counteracted by enhancement of noradrenergic neurotransmission via increased dosages of [?] 30 mg/day (Claghorn and Lesem 1995; Kent 2000). It is likewise hypothesized that the risk of weight gain with mirtazapine is diminished at dosages [?] 30 mg/day (Barkin *et al.* 2000; Fawcett and Barkin 1998b). However, a more recent meta-analysis indicated that mirtazapine was associated with considerable weight gain (average of 1.5 kg) in randomized clinical trials (Domecq *et al.* 2015), and product labeling indicates that weight gain of greater than 7% of body weight has been observed (Merck and Co. 2020).

Use During Pregnancy and Lactation

A study conducted across six countries (Djulus *et al.* 2006) assessed the risk associated with exposure to mirtazapine during pregnancy. Birth outcomes were examined for three groups: pregnant women taking mirtazapine, disease-matched pregnant women taking other antidepressants, and pregnant women exposed to nonteratogens. There were approximately 100 patients per group. The rate of spontaneous abortions in the mirtazapine group (19%) was similar to that in the other antidepressant group (17%) and in the nonteratogen control group (11%). The rate of prematurity was significantly higher in the mirtazapine group (10%) than in the nonteratogen group (2%). The rate of prematurity in the group taking other antidepressants was 7%. The rate of major malformations was not elevated in the mirtazapine group.

In a study of eight women taking mirtazapine while breastfeeding, concentrations of mirtazapine or desmethylmirtazapine were measured in milk and plasma (Kristensen *et al.* 2007). Low infant doses were observed, which led the authors to conclude that the drug is safe for lactating women who breastfeed.

Overdose

Mirtazapine appears to be safe in overdose. In one report (Holzbach *et al.* 1998), the cases of two patients who had overdosed with 30-50 times the average daily dose of mirtazapine were presented. In each case, the patient recovered fully and without any complications.

Symptoms reported in cases of mirtazapine overdose include disorientation, drowsiness, impaired memory, and tachycardia (Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995; Stimmel *et al.* 1997).

A review of 117 mirtazapine overdoses (average ingestion of 450 mg) in Scotland revealed the adverse consequences to be relatively mild (Waring *et al.* 2007). Decreased consciousness was seen in 27% of subjects; 30% demonstrated tachycardia.

A more recent study of overdoses seen at six general hospitals in the United Kingdom between 2000 and 2006 indicated that mirtazapine was of intermediate toxicity between tricyclic antidepressants and venlafaxine on the one hand and SSRIs on the other (Hawton *et al.* 2010). Another study of 239,000 patients in the United Kingdom reported that mirtazapine was significantly more likely than citalopram to be associated with suicide, attempted suicide, or self-harm; however, the number of events was low (Coupland *et al.* 2015). Trazodone and venlafaxine were also associated with more overdose events. That mirtazapine and trazodone--two sedating antidepressants often prescribed for depressed patients with comorbid sleep problems--were both noted to be associated with suicidal behavior raises the possibility that baseline insomnia, rather than specific drug effects, might explain at least some of the increased risk of suicide attempts.

Drug-Drug Interactions

In vitro data suggest that mirtazapine is unlikely to have clinically significant effects on the metabolism of drugs by CYP enzymes (Barkin *et al.* 2000; Fawcett and Barkin 1998b; Kent 2000). Analyses of data from the clinical development program for mirtazapine and post-marketing surveillance reveal no clinically relevant drug-drug interactions from the concomitant use of medications such as opiates, anticonvulsants, analgesics, antihypertensives, diuretics, or nonsteroidal anti-inflammatory drugs (Barkin *et al.* 2000; Fawcett and Barkin 1998b). However, few formal drug interaction studies involving mirtazapine have been conducted (Barkin *et al.* 2000; Fawcett and Barkin 1998b; Holm and Markham 1999). Of note, a study of elderly patients with depression allowed patients to take drugs that were CYP2D6 substrates (Schatzberg *et al.* 2002). In this study, no increase in side effects was observed in these patients compared with patients who were not taking CYP2D6 substrate agents (Schatzberg *et al.* 2002). Because somnolence is a recognized side effect of mirtazapine, excessive sedation may occur when it is used with other agents known to cause CNS depression (e.g, benzodiazepines, antihistamines, ethanol, cannabinoids).

Conclusion

Mirtazapine is derived from the piperazinoazepine class of compounds and thus is structurally unrelated to any other psychotropic medication. Mirtazapine is also unique as an antidepressant because of its 5-HT$_2$, 5-HT$_3$, and a$_2$ receptor antagonist pharmacodynamic profile, which results in enhancement of noradrenergic and serotonergic transmission. It is an antidepressant that has been shown to be efficacious and well tolerated in the treatment of depression, and there are indications that it may be effective in treating a number of other medical and psychiatric conditions. Moreover, mirtazapine may offer a more rapid amelioration of symptoms of depression and anxiety compared with other antidepressants. The most common side effects reported with mirtazapine are somnolence, increased appetite, weight gain, and dry mouth. It otherwise appears to be free of many of the adverse effects typical of SSRIs, especially sexual dysfunction.

Furthermore, mirtazapine appears to be well tolerated and effective in the treatment of geriatric depression and to have benefit as an add-on agent in treating schizophrenia. In addition, mirtazapine is considered to be relatively safe in overdose, with case reports documenting complete and uncomplicated recovery following ingestion of up to 50 times the average daily dose. Finally, mirtazapine appears to be devoid of clinically significant drug-drug interactions, although larger formal clinical trials are still needed to verify this.

CHAPTER 18

Bupropion

History and Discovery

Bupropion was discovered when investigators were searching for an antidepressant with a novel mechanism of action and safer side-effect profile compared with the antidepressants available at that time. Synthesized in 1966, this unique compound, unlike tricyclic antidepressants and monoamine oxidase inhibitors, was found to have antidepressant activity in animal models that are predictive of antidepressant activity in humans (Soroko and Maxwell 1983). Bupropion's tolerability profile is superior to that of selective serotonin reuptake inhibitors (SSRIs), with less weight gain, less sedation, no withdrawal symptoms upon discontinuation, and minimal sexual side effects (Thase *et al.* 2005).

Bupropion first received FDA approval in 1985 and was on the brink of release when a study by Horne *et al.* (1988) reported that 4 of 55 inpatients with bulimia experienced seizures during treatment with the medication. Further research revealed that the risk of seizures increased with dosage, from a risk of 0.3%-0.4% at a dosage of 450 mg/day to a risk of almost 2% at a dosage of 600 mg/day. Bupropion was reintroduced in 1989 with a maximum recommended dosage of 450 mg/day (Davidson 1989). The original immediate-release formulation of bupropion was dosed three times daily (GlaxoSmithKline n.d.). In an effort to improve tolerability and safety, a sustained-release (SR) formulation of bupropion, dosed twice daily, was subsequently introduced (GlaxoSmithKline n.d.), and a once-daily extended-release (XL) formulation became available in 2003 (Bausch Health Companies 2021). Care must be taken to differentiate the XL product from the SR product when prescribing. Bupropion is available in two salt forms. Bupropion hydrochloride 150 mg is approximately equivalent to 174 mg of bupropion hydrobromide. A bupropion hydrochloride/naltrexone hydrochloride combination product is also marketed for the treatment of obesity (Currax Pharmaceuticals 2021; see subsection "Obesity" later in chapter).

Structure-Activity Relations

Bupropion, 2-(tert-butylamino)-1-(3'-chlorophenyl)propan-1-one, is a monocyclic antidepressant and a member of the aminoketone group (Figure 18-1). It was designed as a simple chemical structure that in vivo would result in relatively innocuous metabolites (Mehta 1983). Chemically speaking, bupropion is an organic base with a high degree of both water and lipid solubility, which results in good systemic absorption. Its relatively benign side-effect profile is due to the absence of heterocyclic rings as well as other common functional groups (Mehta 1983).

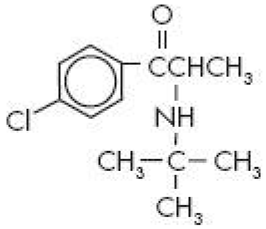

FIGURE 18-1. Chemical structure of bupropion.

It has been noted that bupropion shares some structural and neurochemical properties with sympathomimetics and has a phenylethylamine skeleton similar to that of amphetamine. As may be expected from this structural similarity, a study of false-positive amphetamine urine drug screens found therapeutic use of bupropion to be the most common cause (Casey *et al.* 2011). Despite the similarity, an early study by Griffith *et al.* (1983) comparing the effects of bupropion and amphetamine in individuals with a history of amphetamine abuse concluded that bupropion had little potential for abuse in humans. However, reports have described cases in which bupropion was perceived as a psychostimulant by patients with a previous history of cocaine abuse (Vento *et al.* 2013). Bupropion is also valued as a stimulant of abuse in the incarcerated population (Hilliard *et al.* 2013). This highlights the need to monitor bupropion users for potential abuse, especially those patients with a history of stimulant use disorders.

Pharmacological Profile

Bupropion inhibits the reuptake of dopamine and norepinephrine by acting as a nonselective inhibitor of the dopamine transporter (DAT) and the norepinephrine transporter (NET). Studies show that bupropion also acts as an antagonist to nicotinic acetylcholine receptors. Preclinical data indicate that bupropion does not bind to postsynaptic histamine, a- or b-adrenergic, or serotonin receptors, nor does it inhibit monoamine oxidase (Ascher *et al.* 1995; Baldessarini 2001; Fava *et al.* 2005; Stahl *et al.* 2004). Thus, of the myriad antidepressants now available, bupropion is the only agent without substantial serotonergic activity (Ascher *et al.* 1995; Richelson 1996; Stahl *et al.* 2004). Bupropion's lack of action at histamine and serotonin receptors confers a favorable side-effect profile, including an absence of weight gain, somnolence, and sexual side effects (Settle *et al.* 1999).

Pharmacokinetics and Disposition

Bupropion is rapidly absorbed in the gastrointestinal tract after oral administration (Findlay *et al.* 1981; Jefferson *et al.* 2005). Absorption has been found to be close to 100% (Schroeder 1983). After first-pass metabolism, systemic bioavailability of the drug is decreased. Peak plasma levels occur within 2 hours, 3 hours, and 5 hours for the immediate-release, SR, and XL formulations, respectively (Jefferson *et al.* 2005; Schroeder 1983). Food does not impair absorption, so doses may be administered without regard to meal times. Protein binding ranges from 82% to 88%, which is not high enough to be of clinical importance (Jefferson *et al.* 2005). The elimination half-life for bupropion is 21 (+- 9) hours, and the half-life for hydroxybupropion, the major metabolite of bupropion, is close to 20 (+- 5) hours (Clayton 2007; Jefferson *et al.* 2005). Steady state occurs in 7-10 days. Finally, excretion in the urine occurs with 0.5% of the drug unchanged (Findlay *et al.* 1981; Jefferson *et al.* 2005).

Bupropion is metabolized extensively by the liver. The major metabolite, hydroxybupropion, is hydrolyzed by cytochrome P450 (CYP) 2B6 (Hesse *et al.* 2000; Kirchheiner *et al.* 2003). Whereas CYP2B6 is the primary isoenzyme involved in bupropion's metabolism, other isoforms, including 1A2, 2A6, 2CP, 2D6, 2E1, and 3A4, also play a small role (Hesse *et al.* 2000; Kirchheiner *et al.* 2003).

In examinations of the pharmacokinetics of bupropion in regard to gender, age, and smoking status, no significant effect has been found, and definitive results have been inconclusive (Daviss *et al.* 2006; Hsyu *et al.* 1997; Jefferson *et al.* 2005). One study in elderly patients found evidence for an extended half-life of bupropion and for the accumulation of metabolites (Sweet *et al.* 1995). Because levels of bupropion and its metabolites have been found to be increased in populations with impaired renal and/or hepatic function relative to healthy control subjects (DeVane *et al.* 1990; Jefferson *et al.* 2005; Worrall *et al.* 2004), dosing should be initiated at lower levels in these patients. The manufacturer has recommended that bupropion be used with caution in patients with mild to moderate liver disease and with extreme caution in patients with severe liver disease (GlaxoSmithKline n.d.).

Mechanism of Action

Bupropion inhibits the reuptake of dopamine and norepinephrine by acting as a nonselective inhibitor of the DAT and the NET. Two of its active metabolites--hydroxybupropion and threohydrobupropion--have also been shown in in vitro studies to inhibit both the NET and the DAT (Ascher *et al.* 1995).

Whereas other antidepressants that affect NET receptors are thought to produce their effects by downregulating postsynaptic noradrenergic receptors, bupropion differs in that it decreases the firing rate of neurons in the locus coeruleus in a dose-dependent manner (B. R. Cooper *et al.* 1994; T. B. Cooper *et al.* 1984). Acute administration of bupropion not only decreases the firing of brain stem norepinephrine and dopamine neurons but also increases extracellular norepinephrine and dopamine concentrations in the nucleus accumbens (Fava *et al.* 2005). Furthermore, the efficacy of bupropion and hydroxybupropion has been shown to diminish in animal models when norepinephrine-or dopamine-blocking drugs are administered (Cooper *et al.* 1980; Dwoskin *et al.* 2006).

Studies have demonstrated that bupropion raises dopamine concentrations by causing a rapid and reversible increase in vesicular dopamine reuptake via cellular redistribution of the vesicular monoamine transporter 2 protein. By increasing the presynaptic pool of dopamine available for release, it further augments the concentration of dopamine in the extracellular space, which adds to the therapeutic efficacy of this compound (Dwoskin *et al.* 2006; Rau *et al.* 2005).

Outside of its action on the DAT and the NET, bupropion has been shown to work by noncompetitive inhibition of nicotinic acetylcholine receptors (Dwoskin *et al.* 2006). This action may partially contribute to bupropion's efficacy not only as an antidepressant but also as an agent to facilitate tobacco cessation.

Indications and Efficacy

Primary Indications

Major Depressive Disorder

Bupropion's efficacy in the treatment of major depressive disorder (MDD) is supported by many clinical trials. The drug's three formulations are equally useful for this therapeutic indication (Fabre *et al.* 1983; Lineberry *et al.* 1990). Comparison trials have demonstrated that bupropion is as effective as other classes of antidepressants, including tricyclic antidepressants and SSRIs (Branconnier *et al.* 1983; Clayton *et al.* 2006; Coleman *et al.* 1999, 2001; Croft *et al.* 1999; Feighner *et al.* 1986; Kavoussi *et al.* 1997; Mendels *et al.* 1983; Thase *et al.* 2005; Weihs *et al.* 2000).

The development of bupropion SR launched several comparison studies with SSRIs, all of which demonstrated that bupropion's effectiveness in treating symptoms of depression was equal to that of SSRIs. In most studies, the effective daily dose of bupropion SR was between 300 mg and 400 mg (Coleman *et al.* 1999, 2001; Croft *et al.* 1999; Kavoussi *et al.* 1997; Weihs *et al.* 2000). In a meta-analysis of remission data from all available studies comparing bupropion SR and an SSRI, Thase *et al.* (2005) found that remission rates were essentially the same for the two types of antidepressants. Bupropion SR has also been shown to prevent relapse of depressive symptoms in continuation treatment extending up to 1 year (Weihs *et al.* 2002).

The release of bupropion XL in 2003 also generated several comparison studies. In two 8-week placebo-controlled comparison trials of bupropion XL and escitalopram, pooled analysis confirmed equivalent efficacy of the two agents based on the mean change in Hamilton Rating Scale for Depression (Hamilton 1960) scores (Clayton *et al.* 2006). Similarly, in a double-blind comparison trial of bupropion XL (300-450 mg/day) and the serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine XR (150-225 mg/day), both agents produced similar mean changes in Hamilton Rating Scale for Depression scores, although remission rates were significantly higher with bupropion (Thase *et al.* 2006).

Studies have shown bupropion to be efficacious in the treatment of MDD, not only as monotherapy but also as an augmenting agent with SSRIs or SNRIs (Bodkin *et al.* 1997; DeBattista *et al.* 2003; Fava *et al.* 2003; Ferguson *et al.* 1994; Lam *et al.* 2004; Rush *et al.* 2006; Spier 1998; Stern *et al.* 1983; Trivedi *et al.* 2006). Although the "triple monoamine approach" (i.e., using an SSRI with bupropion to block reuptake of serotonin, dopamine, and norepinephrine) is often a useful strategy, Stewart *et al.* (2014) demonstrated that the addition of bupropion XL at a relatively high dosage (i.e., 450 mg/day) to a similarly high dosage of escitalopram (i.e., 40 mg/day) increased neither the speed of recovery nor the likelihood of recovery from a major depressive episode. Nasr *et al.* (2014) compared the outcomes of patients who received either aripiprazole or bupropion as an adjunct to SSRI treatment. Although no overall differences were found between the two augmenting agents, bupropion was significantly more helpful in treating poor energy and motivation, whereas aripiprazole proved superior in reducing suicidal ideation. This finding suggests that a careful symptom inventory is the best guide in selecting an augmenting agent.

The Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study was the largest protocol-driven study of MDD ever undertaken, with an initial study population of 4,041. A retrospective analysis of this study directly addressed the question of which next-step strategy--medication augmentation or medication switching--yields the best outcome for patients whose symptoms have not improved after an adequate trial of antidepressant monotherapy (Gaynes *et al.* 2012). Findings specific to bupropion suggested that patients who completed an initial 12-week period of citalopram treatment without experiencing complete symptom remission received more benefit from augmenting citalopram with bupropion than from discontinuing citalopram and switching to bupropion.

In August 2022, the FDA approved dextromethorphan-bupropion hydrochloride extended-release tablets for the treatment of MDD in adults (Axsome Therapeutics 2022). Dextromethorphan (DXM) is an *N*-methyl-D-aspartate (NMDA) receptor antagonist with additional effects at serotonin transporters and NETs and nicotinic and sigma-1 receptors (Majeed *et al.* 2021). In an industry-sponsored (Axsome Therapeutics) randomized, double-blind trial of DXM/bupropion (AXS-05) versus bupropion alone (105 mg twice daily), O'Gorman *et al.* (2019) reported that at 6 weeks, 47% of patients treated with DXM/bupropion achieved remission, compared with 16% of those treated with bupropion alone. A follow-up Phase III double-blind, placebo-controlled, industry-sponsored trial (O'Gorman *et al.* 2020) found similar results, with DMX/bupropion being associated with statistically significant reductions in total Montgomery-Asberg Depression Rating Scale (Montgomery and Asberg 1979) scores compared with placebo beginning at week 1.

It was hypothesized that the two drugs may produce more rapid relief from depression than bupropion alone by achieving pharmacological synergy through the targeting of multiple monoamines and receptors. Furthermore, therapeutic plasma levels of DXM are achieved through inhibition of its metabolism by bupropion's actions at CYP2D6. Each extended-release tablet contains 45 mg of DXM and 105 mg of bupropion (Axsome Therapeutics 2022). The recommended dosing strategy is one tablet daily for 3 days, after which the dosage can be increased to one tablet twice daily (except in the context of moderate renal impairment or poor metabolism of CYP2D6), with doses separated by at least 8 hours. The most common adverse reactions include dizziness, headache, diarrhea, somnolence, dry mouth, sexual dysfunction, and hyperhidrosis (Axsome Therapeutics 2022).

Depression in the elderly. Depression in the elderly is often underdiagnosed and may go untreated. Older individuals tend to describe nonspecific somatic symptoms, such as insomnia, anorexia, and low energy, instead of reporting depressed mood (Birrer and Vemuri 2004). Bupropion has been found to be an effective antidepressant in elderly patients (Birrer and Vemuri 2004; Branconnier *et al.* 1983; Weihs *et al.* 2000). A study comparing bupropion SR and the SSRI paroxetine noted that although both agents were effective in treating depression, bupropion SR had a more favorable side-effect profile (Weihs *et al.* 2000). Like bupropion SR, bupropion XL has shown efficacy in the treatment of depression in elderly individuals (Clayton 2007). However, a study examining whether gender-or age-related differences in efficacy exist between SSRIs and bupropion for the treatment of MDD found SSRIs and bupropion to be equally effective in treating depressive symptoms, anxiety/somatic symptoms, and insomnia across all age and gender groups (Papakostas *et al.* 2007).

Depression with decreased energy, interest, and pleasure. Bupropion XL has been studied specifically in depressed patients with a retarded/anergic symptom profile. Jefferson *et al.* (2006) showed that bupropion XL was more effective than placebo in depressed patients with decreased energy, pleasure, and interest. Bupropion's unique norepinephrine-dopamine reuptake inhibitor mechanism of action may play a role in its effectiveness in treating these symptoms (Jefferson *et al.* 2006).

Depression with anxiety symptoms. Studies have demonstrated the effectiveness of bupropion at dosages of 300-400 mg/day in reducing symptoms of anxiety in patients with MDD (Fabre *et al.* 1983). Moreover, bupropion and SSRIs appear to be equally effective in reducing symptoms of anxiety associated with MDD in both the general population and the elderly (Feighner *et al.* 1991; Weihs *et al.* 2000). In 2001, Trivedi *et al.* published results of a study examining the effects of bupropion SR versus sertraline on anxiety in depressed patients, reporting that both bupropion SR and sertraline were superior to placebo in allaying depressive symptoms; however, the treatment of anxiety symptoms did not significantly differ from placebo for either active medication. The study concluded that bupropion and SSRIs were comparable in their antidepressant and anxiolytic effects in patients with MDD. Neither was favored for more specific management of anxiety (Trivedi *et al.* 2001). A meta-analysis comparing the efficacy of bupropion and SSRIs for the treatment of anxiety symptoms in MDD concluded that both classes of medication led to a similar degree of improvement in anxiety symptoms, with no significant difference in the severity of residual anxiety symptoms (Papakostas *et al.* 2008).

Depression with seasonal pattern (seasonal affective disorder).

In 2006, bupropion XL (Bausch Health Companies 2021) became the first medication to receive a labeled indication for the preventive treatment of seasonal depressive symptoms, and it is still the only medication to have received such an indication. A study published in 1992 initially suggested bupropion's efficacy as a treatment for winter depression (Dilsaver *et al.* 1992). In 2005, Modell *et al.* published the results of three prospective randomized, placebo-controlled prevention trials involving 1,042 outpatients with a diagnosis of seasonal major depressive episodes. Patients received 150-300 mg/day of bupropion XL or placebo in autumn while they were still well. Bupropion XL reduced the frequency of emergence of winter depression by 44% and protected against the recurrence of seasonal major depressive episodes. Furthermore, there was no noticeable increase in major depressive episodes following discontinuation of bupropion in the springtime (Modell *et al.* 2005).

Bipolar depression. A small number of early studies demonstrated the advantages of bupropion in the treatment of depression in bipolar disorder (Haykal and Akiskal 1990; Shopsin 1983; Wright *et al.* 1985). Although these investigations yielded positive results, they were limited by small numbers of subjects and lack of placebo control. Several trials have examined the risk of treatment-emergent mania with adjunctive use of bupropion in bipolar disorder. Although there appears to be a lower risk of mania with bupropion and SSRIs than with the SNRI venlafaxine, findings regarding bupropion's efficacy in treating depressive symptoms in bipolar disorder have been mixed (Leverich *et al.* 2006; Post *et al.* 2006; Sachs *et al.* 2007).

Smoking Cessation

In 1997, bupropion SR received FDA approval for use as a smoking cessation aid under the trade name Zyban (GlaxoSmithKline 2006). The beneficial effect of bupropion on smoking cessation was first noted when researchers observed unplanned suspension of smoking in depressed subjects who were being treated with bupropion (reviewed in Hudziak and

Rettew 2004). In a double-blind placebo-controlled trial of bupropion SR therapy for smoking cessation (Hurt *et al.* 1997), 615 subjects received bupropion SR at dosages of 100 mg/day, 150 mg/day, or 300 mg/day for 7 weeks, with a target quit date of 1 week after beginning treatment. Brief counseling was also provided. Rates of smoking cessation at the end of 7 weeks were 29% for the 100 mg/day group, 39% for the 150 mg/day group, and 44% for the 300 mg/day group versus 10% for placebo. At 1 year, rates for the three bupropion dosage groups were 20%, 23%, and 23%, respectively, compared with 12% for the placebo group.

For smoking cessation, the recommended dosing is 150 mg/day for 3 days, then 150 mg twice daily for 7-12 weeks, with patients setting a quit date of 1-2 weeks after treatment has been initiated. In 2003, Ferry and Johnston published a 5-year review of the accumulated efficacy and safety data for bupropion SR since its 1997 approval for smoking cessation. A benefit-risk analysis assuming a 30% 1-year quit rate concluded that for every 10,000 smokers treated with bupropion SR, 19 lives are saved and 86 cases of smoking-attributed morbidity are avoided, whereas the risk of a serious adverse effect from treatment is 0.22% (Ferry and Johnston 2003). More recent data have confirmed that bupropion evidences no increased risk of self-harm, suicide, or depression compared with either varenicline or nicotine replacement therapy (Thomas *et al.* 2013). Use of nicotine replacement therapy together with bupropion has been reported to improve smoking cessation outcomes (Siu and U.S. Preventive Services Task Force 2015).

Obesity

Unlike other classes of antidepressants, bupropion is well known for its lack of association with weight gain. In fact, mild, acute weight loss has been noted in many clinical trials. To further investigate this observation, Gadde *et al.* (2001) conducted a randomized, placebo-controlled trial investigating the tolerability and efficacy of bupropion (100-400 mg/day) for weight loss in 50 obese women. All subjects kept a food journal and were placed on a 1,600 kcal/day diet. At 8 weeks, subjects receiving bupropion had achieved greater weight loss compared with those on placebo. At 24 weeks, responders to bupropion had lost an average of 13% of their baseline body weight (Gadde *et al.* 2001). Following this initial study of bupropion for weight loss, two larger studies confirmed these results (Anderson *et al.* 2002; Jain *et al.* 2002).

In 2014, the FDA approved Contrave (Currax Pharmaceuticals 2021), a bupropion/naltrexone combination, for the treatment of patients who are obese (defined as BMI [?] 30 kg/m^2) or overweight (defined as BMI [?] 27 kg/m^2) and have at least one cardiovascular risk factor (Apovian *et al.* 2013). FDA approval followed studies showing that bupropion/naltrexone combination therapy led to reductions in total and visceral adiposity (Smith *et al.* 2013). A drug safety evaluation of bupropion/naltrexone concluded that it led to greater weight loss compared with two other medications approved by the FDA for the treatment of obesity, orlistat and lorcaserin, but less weight loss compared with topiramate/phentermine combination therapy (Verpeut and Bello 2014). Furthermore, a study using functional MRI demonstrated decreased reactivity to food cues following a course of bupropion/naltrexone therapy (Wang *et al.* 2014).

Other Uses

ADHD

Currently there is no FDA indication for bupropion's use in treating ADHD, although studies have demonstrated that it may be helpful in treating symptoms of ADHD in both children and adults (Conners *et al.* 1996; Simeon *et al.* 1986). Clinical trials in children with ADHD have shown bupropion to be a safe and effective alternative to stimulants for treating this disorder (Conners *et al.* 1996), with efficacy similar to that of methylphenidate reported in one comparison trial (Barrickman *et al.* 1995). Bupropion has also been studied in adults with ADHD and has demonstrated statistically significant symptom improvement in this population (Wilens *et al.* 2001). In a meta-analysis by Peterson *et al.* (2008), long-acting forms of bupropion appeared to exhibit clinical effectiveness similar to that of long-acting stimulants in adults. An open trial by Riggs *et al.* (1998) suggested that bupropion may also be useful for the treatment of ADHD in adolescents with comorbid conduct disorder and substance use disorders. A large review of meta-analyses (Moriyama *et al.* 2013) concluded that bupropion therapy is more effective than placebo but less effective than stimulant therapy in the treatment of ADHD.

Overall, bupropion may be a reasonable alternative to stimulants for treating patients with ADHD and comorbid substance use disorders when clinicians would like to avoid prescribing controlled substances.

Sexual Dysfunction

Bupropion has been found in numerous studies of patients with MDD (using validated questionnaires) to be significantly less likely than SSRIs or SNRIs to cause sexual dysfunction, which has led to investigations of bupropion as an antidote to SSRI-induced sexual dysfunction. A placebo-controlled comparison trial of bupropion SR treatment in 42 patients with SSRI-induced sexual dysfunction concluded that bupropion SR increased both the desire to engage in sexual activity and the frequency of engaging in sexual activity relative to placebo (Clayton *et al.* 2004). Safarinejad *et al.* (2010) demonstrated bupropion's efficacy in reversing SSRI-induced sexual dysfunction in men.

Segraves *et al.* (2001) found that bupropion may be helpful in the treatment of DSM-IV-TR hypoactive sexual desire disorder (HSDD; American Psychiatric Association 2000). Subsequently, a double-blind placebo-controlled trial supported this finding and also revealed increases in sexual arousal, orgasm completion, and sexual satisfaction in women with DSM-IV-TR HSDD who received bupropion (Segraves *et al.* 2004). Additional studies have also demonstrated that bupropion may be helpful for treating sexual disorders in both men and women (Modell *et al.* 2000). In a review of non-testosterone treatment options available for HSDD, Lodise (2013, p. 411) concluded that "bupropion is the primary pharmacological agent that has shown positive results."

Pending Investigations

AXS-05, the combination DXM/bupropion medication that was approved for MDD in August 2022, is also being investigated for the treatment of agitation in Alzheimer's disease and for smoking cessation (Stahl 2019). The FDA granted this agent a Breakthrough Therapy designation for the treatment of Alzheimer's-related agitation in June 2020 after the Addressing Dementia via Agitation-Centered Evaluation-1 (ADVANCE-1) Phase II trial--which compared DXM/bupropion versus bupropion versus placebo in patients with probable Alzheimer's disease with clinically significant agitation--demonstrated statistically significant reductions in the Cohen Mansfield Agitation Inventory (CMAI) relative to both placebo and bupropion alone at week 5 (Axsome Therapeutics 2020). The subsequent Phase III ADVANCE-2 trial was completed in early 2023 (ClinicalTrials.gov NCT03226522), but results have not yet been published. In the Phase II trial of AXS-05 versus bupropion SR for smoking cessation, AXS-05 met its primary outcome of reduced smoking intensity (as measured by number of cigarettes smoked per day) relative to bupropion alone (ClinicalTrials. gov NCT03471767).

Side Effects and Toxicology

Evidence from thousands of clinical trials and millions of patient exposures confirms that bupropion is a safe and generally well-tolerated medication across populations. Because of bupropion's unique mechanism of action and structure, its reported side effects are somewhat different from those of other antidepressants.

In a series of large randomized, placebo-controlled multicenter trials evaluating the safety of bupropion SR in the treatment of depressed outpatients, Settle *et al.* (1999) found that the most commonly reported adverse effects (occurring in > 5% of subjects) were headache, dry mouth, nausea, insomnia, constipation, and dizziness. Only three of these--dry mouth, nausea, and insomnia--occurred at higher rates in patients taking bupropion SR than in those receiving placebo. The rate of discontinuation due to adverse effects was low: 7% for bupropion SR compared with 4% for placebo. Rash, nausea, agitation, and migraine were the most common adverse effects leading to discontinuation (Settle *et al.* 1999). Other adverse events reported in at least 1% of patients receiving bupropion in clinical trials, with a frequency greater than placebo, are pruritus, excessive sweating, tremor, agitation, and anxiety (GlaxoSmithKline n.d.).

The side-effect profile of bupropion XL is similar to that of the other bupropion formulations and compares favorably with that of other controlled-release antidepressants. Compared with venlafaxine XR, bupropion XL was found to be associated with lower rates of dry mouth, nausea, diarrhea, somnolence, sedation, and yawning (Clayton *et al.* 2006). A review by Fava *et al.* (2005) also concluded that bupropion produces much less somnolence compared with SSRIs. Moreover, insomnia, thought to be a particular side effect of bupropion, in fact occurs at rates similar to those seen with SSRIs (Fava *et al.* 2005).

Bupropion SR treatment has been associated with lower rates of sexual dysfunction in comparison with treatment with SSRIs (Thase *et al.* 2005). Similarly, in a head-to-head trial of bupropion XL and venlafaxine XR, Thase *et al.* (2006) found that venlafaxine XR had adverse effects on sexual function whereas bupropion did not.

Less common but potentially harmful adverse effects associated with bupropion include allergic reactions, seizures, and changes in vital signs. Allergic reactions, including rash, arthralgias, fever, and serum sickness-like reactions, have been reported (McCollom *et al.* 2000; Tripathi and Greenberger 1999). Thus, it is important to evaluate any reports of previous hypersensitivity before prescribing bupropion.

Clinicians should screen for a history of seizure disorder, other organic brain disease, or bulimia nervosa before prescribing bupropion. Seizure has been reported at a rate of 0.1% at dosages up to 300 mg/day with bupropion SR, with a dose-related effect (Dunner *et al.* 1998). This rate is similar to rates observed with other newer antidepressants, such as SSRIs and mirtazapine, but is lower than rates associated with therapeutic dosages of tricyclic antidepressants (Montgomery 2005). The incidence of seizure with bupropion XL has not been reported in the literature.

Although cases of spontaneous hypertension with bupropion therapy have been reported, clinical trials across the approved dosage range have shown minimal changes in heart rate and blood pressure, even among patients previously diagnosed with hypertension (Jorenby *et al.* 1999; Settle *et al.* 1999; Thase *et al.* 2008). In a smoking cessation study, patients receiving combination treatment with bupropion SR and a nicotine patch had a higher incidence of new or worsening hypertension compared with patients receiving either treatment alone or placebo (Jorenby *et al.* 1999). Thase *et al.* (2008) conducted a dose-response study to evaluate the potential of bupropion to elevate blood pressure. Bupropion SR dosages of 150-400 mg/day were administered to 296 nondepressed volunteers with mild hypertension. Findings indicated that bupropion SR did not separate from placebo on blood pressure changes. However, clinicians should be aware that elevated blood pressure is a possibility with bupropion therapy and should monitor patients accordingly.

Many agents used to treat depression have been associated with weight gain. This effect is thought to be associated with affinity for the H_1 histamine receptor, which is not a factor with bupropion. In fact, mild weight loss over time, rather than weight gain, has been reported with bupropion treatment (Harto-Truax *et al.* 1983). Studies have shown bupropion XL to be associated with weight loss of 0.1-1.1 kg in the short term compared with placebo, which was associated with a small gain of 0.1-0.8 kg (Jefferson *et al.* 2006; Modell *et al.* 2005; Thase *et al.* 2006). In a longer term study on

depression relapse prevention, Croft *et al.* (2002) observed that patients with higher BMIs at baseline experienced greater weight loss with bupropion XL than did patients with lower baseline BMIs.

Overall, at approved dosages, bupropion is a safe medication for treating depression in most populations and has an excellent tolerability profile. However, high blood levels of bupropion can be fatal. Serious medical consequences, such as hypertension, acidosis, sinus tachycardia, seizures, cardiotoxicity with QRS widening, and even death, have been reported with overdoses of bupropion (Bhattacharjee *et al.* 2001; Curry *et al.* 2005; Shrier *et al.* 2000).

On initiation of bupropion therapy, it is usually not necessary to obtain routine laboratory evaluations, although cases of elevated serum transaminase (Oslin and Duffy 1993) and rare cases of hepatitis (Hu *et al.* 2000) have been reported.

Overall, data on the use of bupropion in pregnancy suggest that there are no impacts on the rate of congenital abnormalities, low birthweight, or premature birth (Turner *et al.* 2019), although data on any long-term risks of prenatal bupropion exposure are lacking. Bupropion and its metabolites are detectable in breast milk, though surveyed mothers largely report no clinically detectable adverse effects in their infants (Drugs and Lactation Database 2015). Although there are some case reports of seizures possibly related to bupropion in breast milk, a retrospective database study comparing women who took bupropion alone, an SSRI alone, or a combination of bupropion and an SSRI found no seizures in infants exposed to bupropion and one seizure in an infant exposed to an SSRI alone (reviewed in Drugs and Lactation Database 2015). Thus, seizures are likely not a major concern in breastfeeding infants of mothers taking bupropion.

Drug-Drug Interactions

As discussed earlier, the main enzyme responsible for the metabolism of bupropion is CYP2B6. Competitive inhibition of metabolism can occur with other drugs processed by this enzyme, such as paroxetine, sertraline, diazepam, clonazepam, clopidogrel, ritonavir, and efavirenz (Hesse *et al.* 2000; Jefferson *et al.* 2005).

Bupropion and its major metabolite, hydroxybupropion, are also strong inhibitors of CYP2D6, an enzyme that plays a role in the metabolism of several classes of medications, including antidepressants, antipsychotics, b-blockers, and antiarrhythmic agents (Wilkinson 2005). Studies of the effects of bupropion on CYP2D6 activity are limited, but results of those conducted suggest that bupropion may increase blood levels of drugs metabolized by CYP2D6, such as desipramine and venlafaxine (Jefferson *et al.* 2005; Kennedy *et al.* 2002). An 8-week open-label study of bupropion

SR co-administered with venlafaxine, paroxetine, or fluoxetine found inhibition of venlafaxine metabolism and higher concentrations of venlafaxine but no significant interaction effects with paroxetine or fluoxetine (Kennedy *et al.* 2002). Because of the effects of CYP2D6 inhibition, dosages of voritioxetine should be reduced by one-half if bupropion is administered concomitantly (Takeda Pharmaceuticals 2021). Other agents known to induce various metabolic pathways have also been shown to affect the metabolism of bupropion. Carbamazepine, which induces CYP2B6, CYP3A4, and CYP1A2 activity, has been shown to decrease bupropion concentrations but increase hydroxybupropion concentrations (Ketter *et al.* 1995).

Bupropion should be used with caution in combination with other psychotropic agents that can lower the seizure threshold, such as tramadol, certain antidepressants, and antipsychotics (Delanty *et al.* 1998; Gardner *et al.* 2000). It should also be used with caution in people who abuse alcohol, because this population may have a higher risk of seizures (Dunner *et al.* 1998). In addition, because bupropion increases dopamine reuptake, additive effects with other dopaminergic agents (e.g., levodopa) are a possibility (Goetz *et al.* 1984).

Conclusion

Bupropion is unique among antidepressants in that it functions as a dopamine and norepinephrine reuptake inhibitor and as an antagonist of nicotinic acetylcholine receptors. Because bupropion has no measurable serotonergic activity, its side-effect profile differs markedly from those of other antidepressants, and it provides a treatment alternative for individuals who cannot tolerate or who do not respond to SSRIs. Although its current FDA-approved indications are limited to the treatment of MDD, seasonal depressive symptoms, tobacco use disorder, and obesity, bupropion has also demonstrated utility in treating pediatric and adult ADHD and in treating sexual disorders/dysfunctions. Bupropion may offer particular utility in treating depression characterized by decreased energy and interest; as an adjunctive antidepressant, with a lower risk of manic switch, for bipolar depression; and for treating depression with comorbid tobacco use disorder, ADHD, obesity, or other substance use disorders. Bupropion may also be used to augment other antidepressants in the treatment of MDD and to reverse SSRI-induced side effects. Its greater tolerability, including low risk of weight gain, minimal sedation, and few sexual side effects, adds to bupropion's value as an effective antidepressant.

CHAPTER 19

Venlafaxine and Desvenlafaxine

Michael E. Thase, M.D.

Venlafaxine and desvenlafaxine are two of the more commonly used members of the serotonin-norepinephrine reuptake inhibitor (SNRI) class of antidepressants. As the first member of the SNRI class to be available to prescribers, venlafaxine became one of the most commonly prescribed antidepressants in the United States across the last 30 years. As their names suggest, venlafaxine and desvenlafaxine are closely related medications: the latter is a commercialized form of the principal metabolite of venlafaxine and, for most people, is likely to convey much of the therapeutic activity of the parent drug. However, in contrast to the analogous relationship between amitriptyline and nortriptyline, desvenlafaxine has not replaced venlafaxine in the pharmacopoeia of antidepressants, perhaps because the potential advantages of the newer drug are largely limited to a relatively small subset of patients, namely those who have trouble metabolizing venlafaxine. As outlined in this chapter, desvenlafaxine nonetheless offers prescribers a potentially useful alternative when an SNRI is clinically indicated and venlafaxine is not a consideration (e.g., provider preference and/or patient history of intolerance).

History and Discovery

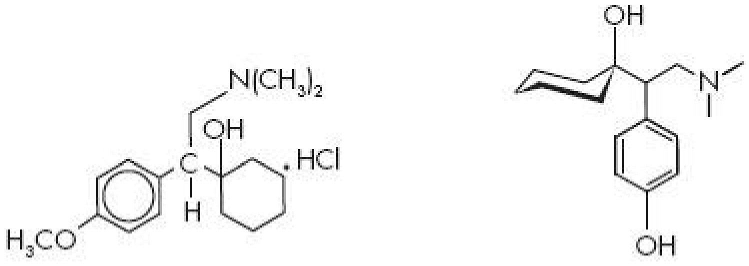
Venlafaxine was developed as the first SNRI in the late 1980s and early 1990s (Bolden-Watson and Richelson 1993; Muth *et al.* 1986). Several early randomized controlled trials (RCTs) suggested that venlafaxine had antidepressant effects comparable to those of tricyclic antidepressants (TCAs), with fewer side effects attributable to anticholinergic and antihistaminergic activity (see, e.g., Einarson *et al.* 1999). An immediate-release (IR) form of venlafaxine was approved by the U.S. FDA for the treatment of major depressive disorder (MDD) in 1994, and the extended-release (XR) formulation was introduced in 1997. Made available after several widely prescribed newer-generation antidepressants (e.g., fluoxetine, sertraline, paroxetine), venlafaxine became one of the leading alternatives for patients who do not respond to selective serotonin reuptake inhibitors (SSRIs).

O-desmethylvenlafaxine (ODV), commonly referred to as desvenlafaxine, is the primary active metabolite of venlafaxine and is also classified as an SNRI. An XR formulation of ODV was developed and tested, and in 2008 desvenlafaxine succinate received FDA approval for use in the treatment of MDD. Compared with venlafaxine, desvenlafaxine has somewhat greater potency for blockade of the norepinephrine transporter (NET), and the succinate formulation has substantially greater bioavailability (Deecher *et al.* 2006).

Generic equivalent products are available for all venlafaxine and desvenlafaxine dosage forms. A new extended-release oral tablet, venlafaxine besylate 112.5 mg (Norwich Pharmaceuticals, Inc.), which has a tablet strength that was not previously available, was approved by the FDA in 2022.

Structure-Activity Relations and Pharmacological Profile

Venlafaxine and desvenlafaxine are bicyclic phenylethylamine compounds and are structurally and chemically unrelated to any other available antidepressants and anxiolytics (Figure 19-1). Venlafaxine and desvenlafaxine inhibit the neuronal reuptake of serotonin (5-HT) and norepinephrine in both in vitro and ex vivo experimental paradigms (Bolden-Watson and Richelson 1993; Muth *et al.* 1986; Owens *et al.* 1997, 2008). Neither drug inhibits monoamine oxidase or has meaningful affinity for muscarinic, cholinergic, histaminergic H_1, or a-adrenergic receptors (Bolden-Watson and Richelson 1993; Muth *et al.* 1986).



Venlafaxine

Desvenlafaxine

FIGURE 19-1. Chemical structures of venlafaxine and desvenlafaxine.

Pharmacokinetics and Disposition

Venlafaxine and desvenlafaxine are well absorbed after oral ingestion and undergo extensive first-pass hepatic metabolism. ODV is the only active metabolite of venlafaxine, and ODV (desvenlafaxine) itself has no active metabolites. Following ingestion of venlafaxine IR, peak plasma concentrations are achieved within 2 hours for venlafaxine and within 3 hours for ODV (Troy *et al.* 1995). Venlafaxine XR is absorbed more slowly than the IR formulation (peak plasma concentrations are achieved within 5.5 hours for venlafaxine and within 9 hours for ODV), which results in lower peak and higher trough plasma concentrations. Steady-state plasma concentrations of both venlafaxine and ODV are reached within 3-4 days of therapy. For extensive (i.e., normal) metabolizers, ODV accounts for at least 70% of the total drug concentration at steady state (Klamerus *et al.* 1992). Venlafaxine and desvenlafaxine exhibit linear kinetics across clinically relevant dosages (i.e., 50-450 mg/day [Klamerus *et al.* 1992]). Both drugs are minimally bound to plasma albumin, and both are primarily eliminated by the kidneys (Howell *et al.* 1993). Clearance of ODV (half-life 10 hours) is slower than that of venlafaxine (half-life 4 hours).

The recommended starting dosage of venlafaxine is 75 mg/day (taken either in divided doses [IR] or once daily [XR]), which is the minimum effective dosage. A lower starting dosage (37.5 mg/day) is often used in older patients or those who have a history of tolerability problems. The maximum approved dosages for the IR and XR formulations are 375 mg/day and 225 mg/day, respectively. The recommended starting dosage of desvenlafaxine is 50 mg/day, which is also the minimum effective dosage; a 25-mg starting dose is available for patients with a history of tolerability problems. The maximum approved dosage is 100 mg/day. Lower dosages of both drugs are recommended for patients with renal insufficiency; lower dosages of venlafaxine are also recommended for patients with liver disease.

Venlafaxine shows a dose-response relationship for efficacy in MDD (Furukawa *et al.* 2019; Thase *et al.* 2006). Desvenlafaxine does not exhibit a positive dose-response curve for efficacy in MDD; drug-versus-placebo differences for 50 mg/day are as large as those observed for higher dosages (Thase *et al.* 2009). It has not been determined whether patients who do not respond to 50 mg/day might benefit from upward titration. As discussed later in this chapter (see "Side Effects and Toxicology"), there is a negative dose-response curve for tolerability. This suggests that any potential additional benefit from dosages above 100 mg/day is offset by increased attrition due to side effects.

Mechanism of Action

Venlafaxine and desvenlafaxine are potent inhibitors of 5-HT reuptake at minimum therapeutic dosages; inhibition of norepinephrine reuptake is lower at these dosages (Bolden-Watson and Richelson 1993; Deecher *et al.* 2006; Owens *et al.* 2008; Vaishnavi *et al.* 2004). Studies using PET to estimate receptor occupancy demonstrate that the minimum effective total daily dose of venlafaxine (75 mg) yields about 80% occupancy of the 5-HT transporter (Voineskos *et al.* 2007). It is thought that the ascending dose-response relationship of venlafaxine is linked to a dose-dependent increase in NET occupancy (Thase and Sloan 2006). Although experimental (Aldosary *et al.* 2022; Harvey *et al.* 2000) and clinical (Davidson *et al.* 2005; Furukawa *et al.* 2019; Thase 1998; Thase *et al.* 2006) data support this hypothesis, significant effects on autonomic measures of noradrenergic function are evident in healthy volunteers at venlafaxine

dosages presumed to be 5-HT selective (i.e., 37.5 mg/day and 75 mg/day [Bitsios *et al.* 1999; Siepmann *et al.* 2007]). One small PET study of venlafaxine-treated depressed patients found a wide range of NET occupancy values, extending from 8% to 61% (Arakawa *et al.* 2019). There is no consensus about the optimal degree of NET inhibition during SNRI therapy.

Indications and Efficacy

Venlafaxine is approved by the FDA for the treatment of MDD, generalized anxiety disorder (GAD), social anxiety disorder, and panic disorder. Desvenlafaxine is approved only for the treatment of MDD.

Major Depressive Disorder

Venlafaxine's antidepressant efficacy at dosages ranging from 75 mg/day to 375 mg/day was established in a large number of RCTs (see Thase and Sloan 2006 for a review). Meta-analyses of studies using active comparators concluded that venlafaxine is one of the more effective newer-generation antidepressants (Cipriani *et al.* 2018; Nemeroff *et al.* 2008; Schueler *et al.* 2011; Smith *et al.* 2002; Thase *et al.* 2001). However, evidence of venlafaxine's superiority over the SSRIs as a class is largely dependent on the large proportion of early studies that used fluoxetine (Cipriani *et al.* 2018; Nemeroff *et al.* 2008), and escitalopram and paroxetine appear to be as effective as venlafaxine in one comprehensive network meta-analysis (Cipriani *et al.* 2018).

The antidepressant efficacy advantage of desvenlafaxine over placebo was established at dosages ranging from 50 mg/day to 400 mg/day (Kornstein *et al.* 2014; Norman and Olver 2021; Thase *et al.* 2009). Only a handful of studies have compared desvenlafaxine with other active antidepressants, and there has been no evidence for its greater efficacy (Cipriani *et al.* 2018; Norman and Olver 2021). A meta-analysis of studies of desvenlafaxine at approved dosages (50-100 mg/day) concluded that its efficacy was similar to that of venlafaxine XR at comparable dosages (i.e., 75-225 mg/day [Coleman *et al.* 2012]).

With respect to other newer antidepressants, venlafaxine has been compared with mirtazapine (Benkert *et al.* 2006; Guelfi *et al.* 2001), bupropion (Hewett *et al.* 2010; Thase *et al.* 2006), duloxetine (Perahia *et al.* 2008), agomelatine (Kennedy *et al.* 2008), and vortioxetine (Alvarez *et al.* 2012; Wang *et al.* 2015). Overall, the results of these studies do not support the hypothesis that venlafaxine routinely conveys an efficacy advantage over other non-SSRI options. Furthermore, the results of these studies suggest that various non-SSRI antidepressants may offer certain tolerability advantages over venlafaxine. For example, in comparison with venlafaxine, mirtazapine and agomelatine were more effective in treating insomnia, agomelatine and bupropion caused less treatment-emergent sexual dysfunction, and vortioxetine produced fewer noradrenergically mediated side effects (e.g., light-headedness [Wang *et al.* 2015]).

Neither venlafaxine nor desvenlafaxine has established efficacy for the treatment of bipolar depression. In one comparative study in patients with bipolar I depression who were being treated with mood stabilizers, adjunctive venlafaxine was associated with somewhat higher rates of treatment-emergent affective switches in comparison with adjunctive paroxetine (Vieta *et al.* 2002). A higher switch rate for venlafaxine was also observed in a study using adjunctive sertraline and bupropion as comparators (Post *et al.* 2006). However, in two studies of bipolar II depression, venlafaxine monotherapy was more efficacious than lithium monotherapy with no greater risk of mood switches (Amsterdam and Shults 2008; Amsterdam *et al.* 2016). Although it is difficult to reconcile these findings, these results do suggest that a subset of patients within the broader bipolar spectrum can be treated safely and effectively with venlafaxine.

In an era in which most depressed patients are first treated with an SSRI, venlafaxine has for nearly three decades been one of the preferred second-line choices for patients who do not respond to SSRI treatment (Thase and Sloan 2006; Thase *et al.* 2000). A meta-analysis of RCTs of patients with SSRI-resistant depression comparing venlafaxine with other second-line antidepressants confirmed a modest advantage for switching outside the SSRI class (Papakostas *et al.* 2008).

Both venlafaxine and desvenlafaxine have demonstrated preventive efficacy in studies of longer-term therapy of MDD (Boyer *et al.* 2015; Rickels *et al.* 2010a; Simon *et al.* 2004). A large long-term study of patients with recurrent depression similarly demonstrated significant prophylactic effects for venlafaxine (versus placebo) after 12 months (Kocsis *et al.* 2007) and 24 months (Keller *et al.* 2007) of maintenance therapy. This study also included a comparison group treated with fluoxetine. Although results were generally comparable across the continuation phase and during the first year of maintenance treatment, a trend suggesting greater efficacy for venlafaxine emerged during the second year of maintenance therapy (Thase *et al.* 2011).

Generalized Anxiety Disorder

Venlafaxine XR was approved by the FDA for the treatment of GAD on the basis of a series of placebo-controlled RCTs (see Thase and Sloan 2006). Across studies, efficacy was established for dosages ranging from 75 mg/day to 225 mg/day, with little evidence of a dose-response relationship. Sustained efficacy across 12 months was subsequently demonstrated in a study using a classic placebo-controlled discontinuation design (Rickels *et al.* 2010b).

With respect to comparative efficacy, venlafaxine XR therapy was found to be significantly more effective than buspirone on some--although not all--measures in one study (Davidson *et al.* 1999). In another RCT, neither venlafaxine nor diazepam was found to be significantly more effective than placebo (Hackett *et al.* 2003). A more recent network meta-analysis of RCTs found that the efficacy of venlafaxine XR was comparable to that of SSRIs in outpatients with GAD (Slee *et al.* 2019).

Social Anxiety Disorder

Venlafaxine XR was approved for the treatment of social anxiety disorder on the basis of a series of RCTs that confirmed its efficacy and safety relative to placebo across up to 6 months of double-blind therapy (see Thase and Sloan 2006). As was the case with GAD, effective dosages ranged from 75 mg/day to 225 mg/day, with little evidence of an ascending dose-response relationship. A recent network meta-analysis found that the comparative efficacy of venlafaxine XR was nominally lower than that of several of the more widely prescribed SSRIs, including escitalopram, paroxetine, and sertraline (Williams *et al.* 2020).

Panic Disorder

The efficacy of venlafaxine XR in treating panic disorder was demonstrated in three placebo-controlled studies of acute-phase therapy (Bradwejn *et al.* 2005; Pollack *et al.* 2007a, 2007b). These studies, which used a 37.5 mg/day starting dosage to minimize side effects, established an effective dosage range for venlafaxine of 75-225 mg/day. Two of the studies included paroxetine (40 mg/day) as an active comparator (Pollack *et al.* 2007a, 2007b). In the first comparison study, two fixed dosages of venlafaxine XR (75 mg/day or 150 mg/day) were comparable to paroxetine in terms of both efficacy and tolerability (Pollack *et al.* 2007a). In the second comparison study, an RCT in which two fixed dosages (75 mg/day or 225 mg/day) were also used, the higher dosage of venlafaxine was significantly more effective than paroxetine on several secondary outcome measures, including the proportion of patients experiencing complete relief from full-symptom panic attacks (70% vs. 58%; Pollack *et al.* 2007b). Finally, a fourth study using a relapse prevention design demonstrated sustained efficacy for venlafaxine XR across 6 months of therapy (Ferguson *et al.* 2007).

Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

The efficacy of venlafaxine therapy in treating PTSD was established in two large placebo-controlled studies (Davidson *et al.* 2006a, 2006b). Results of a network meta-analysis suggested efficacy comparable to that of several SSRIs that have been approved by the FDA for this indication (de Moraes Costa *et al.* 2020). Although no pivotal studies of venlafaxine therapy have been conducted among patients with OCD, the results of a 12-week single-blind study indicated that venlafaxine might be at least as effective as clomipramine and significantly better tolerated (Albert *et al.* 2002).

Premenstrual Dysphoric Disorder

A double-blind RCT evaluated the efficacy of venlafaxine IR in the treatment of premenstrual dysphoric disorder in 157 women across four menstrual cycles (Freeman *et al.* 2001). Dosages ranged from 50 mg/day to 200 mg/day, with adjustments for adverse events or lack of efficacy early in each cycle. Analyses of daily symptom rating scores revealed significantly greater improvement in the venlafaxine group compared with the placebo group at endpoint on the primary factors of emotion, function, physical symptoms, and pain.

Vasomotor Symptoms Associated With Menopause

An extensive research program evaluated the efficacy, tolerability, and safety of desvenlafaxine for the treatment of vasomotor symptoms associated with menopause (Sun *et al.* 2013; Tella and Gallagher 2014). Evidence confirmed the efficacy of desvenlafaxine at dosages of at least 100 mg/day and showed safety and tolerability profiles comparable to those seen in studies of MDD. Despite such findings, the FDA has not approved desvenlafaxine for this indication. Although less extensively studied than desvenlafaxine, venlafaxine is also widely used for the treatment of vasomotor symptoms associated with menopause, with an efficacy profile comparable to that of SSRIs (Davari-Tanha *et al.* 2016; Ensrud *et al.* 2015). Likewise, venlafaxine has been shown to be an effective treatment for hot flashes and related symptoms following total hysterectomy in cancer patients (Ramaswami *et al.* 2015).

Treatment of Children and Adolescents

Neither venlafaxine XR nor desvenlafaxine is approved for the treatment of individuals younger than 18 years. Six studies of venlafaxine XR have been published in pediatric populations: a pair of studies in MDD (Emslie *et al.* 2007), two RCTs in GAD (Rynn *et al.* 2007), one study in social anxiety disorder (March *et al.* 2007), and a large RCT in SSRI-resistant depression (Brent *et al.* 2008). For desvenlafaxine, two adequately powered RCTs of children and adolescents have been published (Atkinson *et al.* 2018; Weihs *et al.* 2018).

Results of the depression studies of venlafaxine XR (pooled $N = 334$) indicated that the drug was significantly more effective than placebo among participants ages 12-17 years but not among those ages 7-11 years (Emslie *et al.* 2007). Overall, venlafaxine XR therapy was associated with an increased risk of treatment-emergent suicidal and aggressive behaviors compared with placebo. In the pair of GAD studies (pooled $N = 330$), venlafaxine XR was significantly more effective than placebo in the pooled data set; one study was unequivocally positive, but the other study failed to find a separation between drug and placebo on the primary outcome measure (Rynn *et al.* 2007). In the social anxiety disorder study ($N = 293$), venlafaxine XR was significantly more effective than placebo on both primary and secondary outcome measures (March *et al.* 2007). Finally, in a large National Institute of Mental Health-funded study of adolescents with a history of nonresponse to antidepressant medication, switching to venlafaxine XR therapy was no more effective--and was somewhat less well tolerated--than switching to another SSRI. Both venlafaxine XR and SSRIs were more effective when used in combination with cognitive-behavioral therapy than when used as monotherapy (Brent *et al.* 2008).

Neither RCT of desvenlafaxine demonstrated efficacy in children and adolescents with MDD. The study by Atkinson *et al.* (2018) randomly assigned 363 subjects--109 children (ages 7-11 years) and 254 adolescents (ages 12-17 years)--to 8 weeks of double-blind therapy with either a lower (20-35 mg/day) or higher (25-50 mg/day) dosage of desvenlafaxine or a matched placebo. Although both dosage ranges showed good tolerability and no evidence of treatment-emergent suicidality, neither group experienced a significantly greater reduction in depressive symptoms at week 8 compared with the placebo group. As 55.9% of the subjects in the placebo group had symptom scores that met criteria for a treatment response at study endpoint, this negative trial obviously lacked design sensitivity.

The multicenter RCT by Weihs *et al.* (2018) also randomly assigned children (*n* = 130; ages 7-11 years) and adolescents (*n* = 209; ages 12-17 years) with MDD to 8 weeks of double-blind therapy. In this investigation, desvenlafaxine (25-50 mg/day, based on body weight) and an active comparator, fluoxetine (20 mg/day), were compared with placebo. The two active drugs were comparably well tolerated by children and adolescents, and neither drug was associated with an increase in suicidal thoughts or behaviors during double-blind treatment. The study was judged to be a failed trial because neither active drug group had a significantly greater reduction in depressive symptoms at week 8 compared with the placebo group. Again, signal detection was compromised by a high placebo response rate (62.6% at study endpoint).

Side Effects and Toxicology

The tolerability profiles of venlafaxine and desvenlafaxine include all of the characteristic side effects associated with 5-HT uptake inhibition (i.e., nausea, insomnia, tremor, and sexual dysfunction) as well as side effects attributable to norepinephrine reuptake inhibition (i.e., sweating, light-headedness, and dry mouth); therefore, therapy with these SNRIs is associated with a somewhat higher side-effect burden than is usual with SSRIs (Schueler *et al.* 2011; Thase and Sloan 2006). In a meta-analysis of patient-level data conducted by Nemeroff *et al.* (2008), for example, 11% of the patients treated with venlafaxine withdrew from therapy because of adverse events, compared with 9% of the patients treated with SSRIs. Because relatively low dosages of desvenlafaxine are now recommended, its side-effect profile in controlled studies tends to be more favorable than that of venlafaxine (Coleman *et al.* 2012). Available evidence suggests that rates of sexual side effects with venlafaxine or desvenlafaxine are comparable to those with SSRIs (Clayton *et al.* 2002; Kennedy *et al.* 2000; Montejo *et al.* 2001, 2019; Serretti and Chiesa 2009).

Venlafaxine and desvenlafaxine do not adversely affect cardiac conduction or lower the seizure threshold at therapeutic dosages. Both drugs are associated with small average increases in pulse rate and dose-dependent increases in the risk of elevated blood pressure (Clayton *et al.* 2009; Thase 1998; Thase *et al.* 2015). In older adults, the risk of treatment-emergent hypertension may approach 10% when venlafaxine dosages of 225 mg/day and higher are used (Wathra *et al.* 2020). To mitigate such risks, it is recommended that blood pressure be documented before initiating therapy and periodically checked during ongoing therapy. At higher therapeutic dosages, venlafaxine is also associated with a reduction in heart rate variability (Davidson *et al.* 2005); this effect may be exaggerated when venlafaxine is prescribed in combination with certain other medications, including mirtazapine or quetiapine (Huang *et al.* 2016).

Like SSRIs, venlafaxine is associated with a small but significant increase in bleeding disorders. For example, in studies of the risk of bleeding following childbirth, venlafaxine was associated with an increased risk of postpartum hemorrhage (ranging from 1% to 4% [Gahr *et al.* 2015; Hanley *et al.* 2016; Palmsten *et al.* 2013]). In one study, the risk of bleeding during the final month of pregnancy was greater for SNRIs than for SSRIs (Hanley *et al.* 2016). Such risks have not yet been shown with desvenlafaxine, but given its substantial similarity to venlafaxine, comparable risks are likely to be demonstrated.

There are no adequate, well-controlled studies of either venlafaxine or desvenlafaxine in pregnant women. Both drugs were classified by the FDA as pregnancy Category C drugs at the time of their approval, which indicated that they should be used during pregnancy only if they are clearly clinically indicated. According to the more recent FDA Pregnancy and Lactation Labeling Rule, which went into effect in 2015, the safety of neither drug has been established in pregnancy. Studies completed to date do not document an increased risk of any specific birth defect (Lassen *et al.* 2016; Richardson *et al.* 2019). Venlafaxine and desvenlafaxine are excreted in human breast milk and therefore should not be taken by women who are breastfeeding.

It is well known that abrupt withdrawal of venlafaxine can result in discontinuation-emergent symptoms such as dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances (Fava *et al.* 2018; Haddad 2001). Available evidence suggests that in comparison with venlafaxine, desvenlafaxine may have somewhat less problematic discontinuation-emergent symptoms (Montgomery *et al.* 2009). To minimize discontinuation symptoms, therapy should be tapered over several weeks when possible, and prescribers should counsel patients not to abruptly stop taking their antidepressant medication.

A number of fatal overdoses of venlafaxine have been reported; there is less clinical experience with overdoses of desvenlafaxine. In nonfatal overdoses of venlafaxine, electrocardiogram changes (e.g., QT interval prolongation, bundle branch block, QRS prolongation), sinus and ventricular tachycardia, bradycardia, hypotension, altered levels of consciousness (ranging from somnolence to coma), serotonin syndrome, and seizures have been reported (Howell *et al.* 2007; Whyte *et al.* 2003).

Findings of studies using pharmacoepidemiological data collected in the United Kingdom suggested that venlafaxine may be more lethal in overdose than SSRIs, albeit less so than TCAs (Buckley and McManus 2002; Hawton *et al.* 2010). Because the statistical measure used in these studies, the Fatal Toxicity Index (Henry 1989), is based on the number of overdose deaths per million prescriptions, findings are subject to use biases, in that the patients who are treated with venlafaxine in the current prescribing environment tend to have more severe and resistant psychiatric illnesses compared with patients who are treated with SSRIs and thus may have a greater inherent suicide risk (Mines *et al.* 2005; Rubino *et al.* 2007). Nevertheless, venlafaxine's apparent higher lethality in overdose might be attributable to adverse effects on the seizure threshold (Whyte *et al.* 2003) and on cardiac conduction (Howell *et al.* 2007) at extremely high plasma levels.

Drug-Drug Interactions

Venlafaxine undergoes extensive metabolism in the liver by the cytochrome P450 (CYP) enzyme system, in particular by the CYP2D6 isoenzyme, which is the pathway for the conversion of venlafaxine into ODV. People who are poor metabolizers of CYP2D6 thus have unusually low plasma levels of the metabolite ODV (Preskorn *et al.* 2009). This effect is amplified among patients who are also poor metabolizers via CYP2C19 (Kringen *et al.* 2020). There is evidence that such patients may be less likely to benefit from treatment with venlafaxine than patients who are normal or extensive metabolizers (Lobello *et al.* 2010; Shams *et al.* 2006). Patients who are known to be poor metabolizers via these CYP enzymes would likely be better candidates for therapy with desvenlafaxine than the parent drug.

In vitro and in vivo studies have shown that venlafaxine and ODV are weak inhibitors of CYP2D6 and cause little or no inhibition of other CYP isoenzymes, including 1A2, 2C9, 2C19, and 3A4 (Ball *et al.* 1997; Oganesian *et al.* 2009; Owen and Nemeroff 1998).

Use of venlafaxine or desvenlafaxine is contraindicated in patients taking monoamine oxidase inhibitors because of the risk of serotonin syndrome. As with TCAs and SSRIs, venlafaxine or desvenlafaxine should not be initiated until 2 weeks after discontinuation of a monoamine oxidase inhibitor, and monoamine oxidase inhibitor therapy should not be initiated until at least 7 days after discontinuation of venlafaxine or desvenlafaxine.

Conclusion

Venlafaxine, the first member of the SNRI class in the United States and much of the world, is one of the more effective newer-generation antidepressants, with an overall safety profile that is intermediate between that of SSRIs and that of TCAs. There is evidence of an efficacy advantage for venlafaxine over fluoxetine and perhaps over several other SSRIs; however, such an advantage has not been specifically demonstrated against escitalopram and paroxetine. Venlafaxine's treatment efficacy has also been established in GAD, social anxiety disorder, and panic disorder, although there is no evidence of greater efficacy compared with SSRIs. Desvenlafaxine, which is approved only for the treatment of MDD, has several advantages relative to venlafaxine, including simpler dosing and metabolism that is not dependent on CYP2D6.

CHAPTER 20

Duloxetine, Milnacipran, and Levomilnacipran

Serotonin-norepinephrine reuptake inhibitors (SNRIs) are a class of monoamine reuptake inhibitors that have been found effective for the treatment of major depressive disorder (MDD). They represent another tool for use by providers in patients who do not respond to selective serotonin reuptake inhibitors (SSRIs), or for whom the side effects of SSRIs are found to be intolerable. In this chapter we provide an overview of the pharmacology and the accumulated evidence for the indications, efficacy, tolerability, and safety of the SNRIs duloxetine, milnacipran, and levomilnacipran.

History and Discovery

Duloxetine was first synthesized in the late 1980s and subsequently patented in 1991. It was approved by the U.S. FDA for the treatment of MDD and diabetic neuropathy in the third quarter of 2004 and has subsequently been approved to treat generalized anxiety disorder (GAD), fibromyalgia, and chronic musculoskeletal pain. This long delay after the initiation of clinical investigations was the result of the drug's initial testing in depressed patients at low dosages of 5-20 mg/day, which were not efficacious. Duloxetine has now received approval almost worldwide.

Milnacipran has been approved by the FDA to treat fibromyalgia but has not received an indication for any psychiatric conditions. However, it has been used to treat depression and has received approvals from other countries for the treatment of depression. Levomilnacipran, the active enantiomer of milnacipran, was approved to treat MDD in the United States in 2013 and in Canada in 2015.

Structure-Activity Relations

Duloxetine, milnacipran, and levomilnacipran (Figure 20-1) are medications with antidepressant properties that can act as inhibitors of both serotonin (5-hydroxytryptamine) and norepinephrine reuptake. Whereas SSRIs target only the serotonin transporter (5-HTT), these dual-acting medications have the potential to inhibit both the 5-HTT and the norepinephrine transporter (NET). Collectively, these three medications belong to the class of medications called SNRIs. Several lines of evidence must be considered, however, to determine at which concentrations SNRIs are indeed effective dual-reuptake inhibitors. This is of crucial importance in estimating their potency in clinical settings.

Pharmacological Profile

In Vitro Assessments

The first data to consider in determining the biochemical profile of reuptake inhibitors are their affinity values for membranal carriers. Finding these values involves determining the concentration of a medication necessary to displace 50% of the specific binding of a standard ligand for a given transporter subtype in a cell lysate preparation. This technique generally provides rough estimates of the potential for drugs to inhibit reuptake. Levomilnacipran has stronger affinity for both serotonin and norepinephrine uptake transporters and stronger inhibition of both transporters than does the racemic mixture of milnacipran (Table 20-1).

In Vivo Assessments

Ideally, the potency of reuptake inhibitors in animal experiments should be assessed in vivo with the medications administered peripherally. One common technique involves the use of microdialysis studies, in which extracellular levels of neurotransmitters are estimated from the perfusion of artificial cerebrospinal fluid. Data generated with duloxetine indicate that it first increases levels of serotonin in the rat brain, and with escalating dosage it then increases levels of norepinephrine (Koch *et al.* 2003). In the case of milnacipran, levels of serotonin and norepinephrine are generally increased to the same extent (in guinea pigs [Moret and Briley 1997]), although pronounced regional differences have been observed (Bel and Artigas 1999). Levomilnacipran increases rat cortical extracellular levels of norepinephrine and serotonin, with a norepinephrine-to-serotonin potency ratio of 2:1 (Auclair *et al.* 2013).

Potency ratios can also be assessed in vivo with electrophysiological approaches. Specifically, by determining the capacity of reuptake inhibitors to suppress the firing of norepinephrine and serotonin neurons, one can obtain reliable potency estimates. As reuptake transporters are inhibited from their peripheral injection in a dose-dependent manner, there will be an accumulation of serotonin and norepinephrine at the cell body level of those neurons that will activate their respective autoreceptors, thereby decreasing their firing activity. Use of this technique revealed that duloxetine suppresses the firing rate of serotonin neurons by 50% with an intravenous dose of 0.1 mg/kg and suppresses the firing rate of norepinephrine neurons with 0.5 mg/kg (Kasamo *et al.* 1996). This in vivo ratio of 1:5 is quite different from the in vitro affinity ratio of 1:44 (Auclair *et al.* 2013; see Table 20-1). In contrast, use of the same technique revealed that the dose of milnacipran necessary to inhibit the firing rate of serotonin neurons by 50% is 5.7 mg/kg (Mongeau *et al.* 1998). The latter results therefore suggest that milnacipran (and levomilnacipran) is a much less potent inhibitor of serotonin reuptake than is duloxetine.

Assessments of Serotonin and Norepinephrine Reuptake in Humans

Reuptake of neurotransmitters cannot be assessed as directly in humans as it can be in the brains of laboratory animals. However, several approaches can provide useful estimates. For instance, serotonin reuptake inhibition can be estimated with blood platelet uptake of radioactive serotonin, because platelets do not synthesize serotonin and they contain a 5-HTT that is nearly identical to the one present on serotonin neurons in the brain. Because more than 90% of the serotonin present in the blood is in platelets, whole-blood serotonin depletion by a reuptake inhibitor is an even simpler measure. Use of a peripheral (platelet) assay reveals that duloxetine produces a dose-dependent depletion of the serotonin level that reaches about 60% with a dosage of 60 mg/day, an effect still significantly inferior to that seen with 100 mg/day of the tricyclic antidepressant (TCA) clomipramine (Turcotte *et al.* 2001). Milnacipran produces only a 64% inhibition of serotonin uptake with the usual recommended dosage of 100 mg/day (Palmier *et al.* 1989). By comparison, platelet assays revealed that SSRIs produce greater than 80% inhibition of serotonin uptake at clinically effective dosages (Gilmor *et al.* 2002).

Occupancy of the 5-HTT in the human brain can be assessed directly through PET studies using ligands of this transporter labeled with carbon 11. All commonly used SSRIs and venlafaxine produce 80% occupancy of the 5-HTT at their minimum effective dosages in depression (Meyer *et al.* 2004). A duloxetine daily dosage of 60 mg, but not 40 mg, produces a sustained 80% occupancy (Takano *et al.* 2006). PET studies show that daily dosages of milnacipran 100 mg and 200 mg produce 5-HTT occupancies of 40% and 60%, respectively (Nogami *et al.* 2013). To our knowledge, levomilnacipran has not been tested with this approach.

Researchers have attempted to assess occupancy of the NET in the human brain with PET. However, issues remain regarding the specificity of the reboxetine derivative used in several reports (i.e., the lack of a plasma concentration-occupancy relation [Takano *et al.* 2014]). A variety of peripheral measures can, however, be used. In particular, the intravenous tyramine pressor test has produced consistent results. Tyramine penetrates peripheral norepinephrine terminals through the NET and releases norepinephrine in a calcium-independent manner, thereby transiently elevating systolic blood pressure. Any drug that effectively blocks the NET attenuates this pressor response in a dose-dependent manner. Whereas the SSRIs paroxetine and sertraline do not affect pressor response, the TCAs desipramine, nortriptyline, and clomipramine attenuate the pressor response, as do the selective norepinephrine reuptake inhibitors maprotiline, reboxetine, and atomoxetine (Blier *et al.* 2007; Gobbi *et al.* 2003; Harvey *et al.* 2000; Turcotte *et al.* 2001). Venlafaxine significantly attenuates the tyramine response in depressed patients only at dosages in the range of 225-375 mg/day (Blier *et al.* 2010; Debonnel *et al.* 2007). Duloxetine exerts a clear effect starting at 120 mg/day (Vincent *et al.* 2004), whereas milnacipran and levomilnacipran have not yet been tested in this model. A variety of other peripheral measures suggest that duloxetine may begin to inhibit norepinephrine reuptake at 60 mg/day (Chalon *et al.* 2003; Vincent *et al.* 2004).

Taken together, these results obtained in humans indicate that duloxetine is a potent serotonin reuptake inhibitor at 60 mg/day. A recent report found that NET occupancy by duloxetine was 29.7% at 20 mg, 30.5% at 40 mg, and 40.0% at 60 mg. The estimated dose of duloxetine inducing 50% NET occupancy was 76.8 mg, and the estimated plasma drug concentration inducing 50% NET occupancy was 58.0 ng/mL (Moriguchi *et al.* 2017).

Milnacipran appears to preferentially block norepinephrine reuptake, as has easily been demonstrated in the brains of laboratory animals even at low doses (Bel and Artigas 1999; Mongeau *et al.* 1998), whereas blockade of serotonin reuptake can only be documented with high doses. In humans, robust serotonin reuptake inhibition (> 80% transporter blockade) appears to be achieved only with supratherapeutic doses (i.e., 300-400 mg; Palmier *et al.* 1989). Similar preclinical results have been obtained with levomilnacipran (Auclair *et al.* 2013).

Mechanism of Action

SNRIs produce rapid inhibition of reuptake transporters in the brain, but their antidepressant effects are generally not seen for at least 2 weeks. Extensive electrophysiological and microdialysis studies in laboratory animals have consistently shown a similar delay before SNRIs produce a net enhancement of serotonin and/or norepinephrine transmission (see Blier 2006 for a review). This delay may occur because, as a result of 5-HTT inhibition, potent serotonin reuptake inhibitors initially suppress the firing of serotonin neurons through activation of serotonin type 1A autoreceptors on neuron cell bodies. After 2-3 weeks of sustained administration, these autoreceptors desensitize, and the serotonin neuronal firing rate returns to normal. At this point, there is a net enhancement of serotonin transmission in the forebrain (Blier and De Montigny 1983).

In the case of drugs that inhibit the NET, the firing rate of norepinephrine neurons is promptly diminished through activation of a_2-adrenergic autoreceptors on neuron cell bodies. After 2-3 weeks of sustained administration, the firing rate remains attenuated because the cell body a_2-adrenergic autoreceptors do not become desensitized. In contrast, a_2-adrenergic autoreceptors on norepinephrine terminals generally become desensitized with sustained administration, which leads to a net enhancement of norepinephrine transmission in the forebrain (Invernizzi and Garattini 2004; Rueter *et al.* 1998a, 1998b; Szabo and Blier 2001).

Pharmacokinetics and Disposition

Absorption and Distribution

Table 20-2 summarizes the pharmacokinetics of duloxetine, milnacipran, and levomilnacipran.

Duloxetine	12 hours	3 days	1A2 (potent) 2D6 (potent)	Linear
Milnacipran	8 hours	2 days	None	Linear
Levomilnacipran	12 hours	3 days	3A4	Linear

Note. CYP = cytochrome P450.

Duloxetine

Duloxetine is available in capsules that contain enteric-coated pellets. According to current product labeling, Cymbalta capsules and generic equivalents should be swallowed whole and not chewed, crushed, sprinkled on food, or mixed with liquids (Eli Lilly 2017). Drizalma capsules can be administered whole; can be opened and the pellets sprinkled on applesauce; or can be mixed with water for nasogastric tube administration (Sun Pharmaceutical 2019). Full instructions are provided in the product labeling. Duloxetine is rapidly absorbed after oral administration, and its absorption is not altered by food. Duloxetine's plasma level is proportional to dose, up to a maximum of 60 mg twice daily. It is highly (about 90%) bound to its plasma proteins. Its plasma elimination half-life is approximately 12 hours (Sharma *et al.* 2000). With repeated administration, duloxetine takes approximately 3 days to reach a steady-state level.

Milnacipran and Levomilnacipran

Milnacipran and levomilnacipran have low (13% and 22%, respectively) and nonsaturable plasma protein binding. They are rapidly absorbed after oral administration and have high bioavailability, and their absorption is not affected by food intake. They have no active metabolites, and their elimination half-life is 8 hours. Steady-state levels are thus achieved within 3 days, with no drug accumulation occurring during prolonged dosing, and milnacipran and levomilnacipran are cleared from the body within 3 days of treatment cessation.

Metabolism and Elimination

Duloxetine

Duloxetine is extensively metabolized through various pathways (Skinner *et al.* 2003). Numerous metabolites are found in circulation, none of which is believed to contribute to duloxetine's therapeutic activity. Duloxetine is metabolized mainly by cytochrome P450 (CYP) 1A2 and 2D6 isoenzymes.

Milnacipran and Levomilnacipran

The CYP system is not involved in the metabolism of milnacipran or levomilnacipran (Briley 1998; Chen *et al.* 2015). However, these compounds are inhibitors of CYP3A4, and levomilnacipran at high dosages can interact with other CYP3A4 inhibitors (Allergan 2019; Forest Pharmaceuticals 2009; Hiemke *et al.* 2018). The metabolism of milnacipran

and levomilnacipran is mainly mediated through phase II conjugation. Milnacipran and levomilnacipran are eliminated by the kidneys; approximately 50%-60% of the drugs are recovered in the urine as parent compounds and 20% as their glucuronide conjugates. The remainder of the metabolites are excreted mainly as an *N*-dealkyl metabolite and its glucuronide conjugate and in negligible amounts as an *N*-didealkyl metabolite and a hydroxy metabolite (Brunner *et al.* 2015; Chen *et al.* 2015; Puozzo and Leonard 1996; Puozzo *et al.* 2002).

Indications and Efficacy

Duloxetine is FDA approved for use in the treatment of MDD, GAD, diabetic peripheral neuropathic pain, fibromyalgia, and chronic musculoskeletal pain. Although milnacipran is used for the treatment of MDD in various countries, it has not yet received FDA approval for that indication. In the United States, milnacipran is approved only for the treatment of fibromyalgia. Levomilnacipran is approved only for the treatment of MDD. Clinical practice has shown us the efficacy of these two molecules in both conditions, despite the lack of controlled studies, because of the fact that levomilnacipran is the active enantiomer of milnacipran.

It is recommended that dosing for duloxetine start at 20 mg bid and increase to 40-60 mg/day (the target dosage) within 1 week. The maximum recommended dosage is 120 mg/day. For milnacipran, dosing should begin at 12.5 mg for day 1; increase to 25 mg (12.5 mg twice daily) for days 2 and 3; and increase to 50 mg (25 mg twice daily) for days 4-7. The dosage may then be increased by 50 mg/week to a target dosage of 100 mg/day. The maximum recommended dosage of milnacipran in fibromyalgia is 200 mg/day. For levomilnacipran, the starting dosage is 20 mg/day (taken in a single dose), but it is recommended that this be increased to 40 mg/day (the minimum effective dosage) after 2 days. The dosage can then be increased, over intervals of 2 or more days, to 80 mg/day and then to 120 mg/day, according to tolerability and response. Table 20-3 provides the formulations and dosing for duloxetine, milnacipran, and levomilnacipran as described in the manufacturers' prescribing information.

Major Depressive Disorder

Duloxetine

Duloxetine has been extensively evaluated in placebo-controlled studies as well as active comparator studies of the efficacy and safety of its antidepressant action. An extensive systematic review by Rodrigues-Amorim *et al.* (2020) provided support for the safety and efficacy of duloxetine for treating MDD. Head-to-head comparisons with SSRIs and SNRIs have yielded mixed results, which appear to be influenced by dosing regimens (Cipriani *et al.* 2012; Rodrigues-Amorim *et al.* 2020). Overall, no statistically significant difference in efficacy has been found between duloxetine and other drugs used to treat MDD.

Milnacipran

A meta-analysis of three short-term (4-to 8-week) double-blind, acute efficacy multicenter trials in inpatients and outpatients with moderate to severe depression concluded

that milnacipran provides a superior antidepressant effect compared with placebo at dosages of 50 mg and 100 mg twice daily but not at a dosage of 25 mg twice daily (Lecrubier *et al.* 1996; Macher *et al.* 1989).

Several studies have compared milnacipran with SSRIs or TCAs. Milnacipran was noted to have equal efficacy but superior tolerability relative to the TCA imipramine (Puech *et al.* 1997). Two meta-analyses concluded that evidence was insufficient to suggest a difference in response rates between milnacipran and any SSRI (Nakagawa *et al.* 2009; Papakostas and Fava 2007). A 24-week randomized, double-blind study demonstrated the safety, tolerability, and efficacy of flexible dosages of milnacipran and venlafaxine (100-200 mg/day) in treating MDD (Olie *et al.* 2010).

Levomilnacipran

Four of five controlled studies (involving a total of 3,020 patients) reported effectiveness for the 40-120 mg/day dosage range of levomilnacipran in patients with MDD ages 18-80 years. No controlled active comparator study has yet been published (Faquih *et al.* 2019; Wagner *et al.* 2018).

Generalized Anxiety Disorder

Duloxetine

Duloxetine was shown to be effective in reducing symptoms of GAD in 11 placebo-controlled trials (reviewed in Rodrigues-Amorim *et al.* 2020). Furthermore, duloxetine was found to be more effective and better tolerated compared with other antidepressants (i.e., escitalopram and venlafaxine).

Milnacipran and Levomilnacipran

No studies to date have examined milnacipran or levomilnacipran for the treatment of GAD.

Neuropathic and Chronic Pain

Duloxetine

TCAs and SNRIs clearly produce significant relief of physical symptoms, such as pain in depression and in a variety of pain syndromes (Stahl *et al.* 2005). Duloxetine exerts a prompt and substantial analgesic effect over and above its antidepressant action (Perahia *et al.* 2006). Potentiation of the activity of serotonin and norepinephrine is believed to result in the inhibition of central pain through descending modulatory pathways (Sussman 2003).

In an 8-week study, duloxetine at a fixed dosage of 60 mg/day significantly reduced pain measures from baseline to endpoint compared with placebo in patients with MDD and at least moderate pain. At 8 weeks, the mean average pain score on the Brief Pain Inventory--Short Form was close to 3, which can be considered a mild level of pain compared with the moderate or higher levels of pain indicated by baseline scores (5.8 [Brecht *et al.* 2007]). Similarly, elderly patients with depression who received duloxetine 60 mg/day for 8 weeks showed significantly greater improvement in back pain scores and the amount of time in pain compared with patients who received placebo (Raskin *et al.* 2007). In a randomized controlled trial evaluating the efficacy of duloxetine 60 mg/day in patients with MDD and associated painful physical symptoms, the drug was superior to placebo in reducing overall, shoulder, and back pain as well as time spent in pain (Detke *et al.* 2002b).

Duloxetine has also been shown to be effective in the management of postoperative pain. In a recent meta-analysis of 13 studies, duloxetine led to decreased postoperative pain at 24 and 48 hours as well as decreased opioid use at 24 and 48 hours. Postoperative conditions studied included lumbar surgery, hysterectomy, hip surgery, knee replacement, gynecological surgery, and mastectomy (de Oliveira Filho *et al.* 2020).

Milnacipran and Levomilnacipran

The capacity of milnacipran to relieve chronic pain has been reported in open trials. However, in a study of 40 adults with chronic low back pain, there were no significant differences in primary or secondary outcomes between milnacipran 100-200 mg/day and placebo (Derry *et al.* 2015). Another randomized controlled trial comparing milnacipran and placebo for idiopathic neuropathy pain was terminated because of lack

of recruitment (NCT01288937). There have been no studies evaluating levomilnacipran for the treatment of pain.

Fibromyalgia

Duloxetine

Seven randomized controlled trials have examined the safety and efficacy of duloxetine for the treatment of pain associated with fibromyalgia, and all favored duloxetine. In a meta-analysis of these studies, which included 2,642 adults with fibromyalgia, treatment with duloxetine led to greater pain relief than placebo. However, the use of duloxetine was associated with more adverse events. Dosing at 60 mg/day led to fewer withdrawal effects than 120 mg/day (Lian *et al.* 2020). A recent study of juvenile fibromyalgia in 184 youth had mixed results. Although duloxetine was not more effective than placebo in terms of pain severity at 24 hours, significantly more youth who received duloxetine had [?] 30% and [?] 50% reductions in pain severity than those who received placebo (Upadhyaya *et al.* 2019).

Milnacipran and Levomilnacipran

An initial placebo-controlled study of milnacipran in fibromyalgia patients found that 37% of those who received 100 mg of milnacipran twice daily experienced a significant reduction (50% or more) in pain intensity compared with 14% of those who received placebo (Vitton *et al.* 2004). Subsequent studies led to milnacipran's approval in the United States for treating fibromyalgia (Hauser *et al.* 2011). There have been no studies evaluating levomilnacipran in the treatment of pain.

Stress Urinary Incontinence

Duloxetine has been shown to be efficacious in the treatment of stress urinary incontinence, with 40 mg twice daily being the recommended dosage (Li *et al.* 2013). Serotonin and norepinephrine increase excitatory glutamate transmission in Onuf's nucleus in the sacral spinal cord, which facilitates urethral sphincter contraction (Thor 2003). This presumably is the mechanism underlying duloxetine's beneficial effects in the treatment of this problem.

Side Effects and Toxicology

Duloxetine

The safety and tolerability of duloxetine at a dosage range of 40-120 mg/day have been assessed in a number of clinical trials. In an 8-month study, the most common treatment-emergent adverse events were nausea, dry mouth, vomiting, yawning, and night sweats (Pigott *et al.* 2007). Most of these effects emerged early, within the first 8 weeks of treatment. Other studies have reported insomnia, somnolence, headaches, ejaculation disorders, diarrhea, constipation, and dizziness as common adverse events with duloxetine use (Detke *et al.* 2002a, 2002b; Khan *et al.* 2007; Nierenberg *et al.* 2007).

The incidence of nausea associated with duloxetine appears to be comparable to that associated with other SSRIs and SNRIs. Nausea is transient and is usually experienced

on treatment initiation. A starting dosage of 60 mg/day appears to provide the best combination of clinical response and tolerability (Bech *et al.* 2006; Pritchett *et al.* 2007). Clinicians may, however, consider starting at a lower dosage (30 mg/day) for patients in whom tolerance is a concern. A tolerability study of duloxetine in 137 patients found a starting dosage of 30 mg/day to be associated with a lower rate of nausea than a starting dosage of 60 mg/day (16% vs. 33%, respectively) (Dunner *et al.* 2005). A separate study including 4,313 patients found the 30 mg/day starting dosage to be preferred by the majority of female patients (Wilhelm *et al.* 2012). The initial tolerability of duloxetine 60 mg/day can be improved if the drug is taken with food; when taken with food, the 60 mg/day initial dosage has tolerability comparable to an initial dosage of 30 mg/day (Whitmyer *et al.* 2007).

Duloxetine has not been associated with weight gain, and in fact in one study it was noted to be associated with a mean weight loss of 1 kg (Nierenberg *et al.* 2007). This decrease significantly differed from the lack of effect that placebo and escitalopram had on weight.

Changes in blood pressure and heart rate associated with duloxetine treatment do not appear to be clinically significant. Pooled data from 735 patients receiving duloxetine 40-120 mg/day showed that 0.7% experienced a 10 mm Hg increase in systolic or diastolic blood pressure versus 0.4% of patients receiving placebo. Heart rate was increased by less than 1 beat per minute (Schatzberg 2003).

Rates of sexual dysfunction, including anorgasmia, erectile dysfunction, delayed ejaculation, and decreased libido, appear to be low with duloxetine. Researchers found that after 8 months, categorical outcomes shown on a questionnaire about changes in sexual functioning did not differ significantly between duloxetine-and escitalopram-treated groups (Pigott *et al.* 2007). In clinical practice, however, any drug that strongly inhibits serotonin reuptake has the potential to cause problematic sexual dysfunction in a significant proportion of patients.

A significantly higher rate of discontinuation of treatment was reported among patients who were randomly assigned to receive duloxetine compared with those who were assigned to receive escitalopram or venlafaxine (Cipriani *et al.* 2012). It appears that study participants who discontinue duloxetine because of adverse events often do so early on in treatment (Nierenberg *et al.* 2007; Perahia *et al.* 2008; Pigott *et al.* 2007), which may indicate poorer initial tolerability.

A systematic search of accumulated data for in utero exposure to duloxetine identified 16 major congenital malformations occurring in 668 infants, yielding a relative risk estimate of 0.8 (Lassen *et al.* 2016). Infant exposure to duloxetine through breast milk is less than 1% of the maternal weight-adjusted dosage (Andrade 2014). These figures suggest that duloxetine can be safely used during pregnancy and lactation.

Milnacipran and Levomilnacipran

An analysis of a database of more than 3,300 patients concluded that the adverse event profile of milnacipran in MDD was comparable to that of SSRIs, except that SSRIs were associated with a higher frequency of nausea and anxiety, whereas milnacipran was associated with a higher incidence of dysuria (Puech *et al.* 1997). Weight gain is uncommon, but sedation may be reported. Although data on rates of sexual dysfunction with milnacipran have not been reported, the incidence is estimated to be low compared with that associated with venlafaxine and SSRIs (Stahl *et al.* 2005). The lower incidence of nausea and sexual dysfunction with milnacipran relative to SSRIs may be taken as indirect evidence of milnacipran's lower potential for serotonin reuptake inhibition, given that these two treatment-emergent adverse events are classically induced by potent serotonin reuptake inhibitors.

Blood pressure increases with milnacipran are minimal. A 12-week randomized, double-blind study comparing milnacipran dosages of 100 mg/day and 200 mg/day versus fluoxetine 20 mg/day in 289 depressed inpatients found no significant changes in blood pressure in any of the groups (Guelfi *et al.* 1998). Tachycardia (defined as a heart rate greater than 100 beats per minute) was seen in 0% of patients receiving fluoxetine, 3% of patients receiving milnacipran 100 mg/day, and 6% of patients receiving milnacipran 200 mg/day. A review of more than 4,000 patients taking milnacipran for MDD showed that the mean increase in blood pressure was less than 1 mm Hg, and the mean increase in heart rate was 4 beats per minute (Puech *et al.* 1997). Given that an increase in heart rate is a thumbprint of potent norepinephrine reuptake inhibition, this increase is consistent with the capacity of milnacipran to effectively block norepinephrine reuptake. No cardiotoxicity has been reported with overdoses of up to 2.8 g/day, which is 28 times the recommended daily dosage (Montgomery *et al.* 1996).

An analysis of the long-term safety of milnacipran (in 715 patients with MDD receiving milnacipran for > 6 months and 189 patients receiving it for > 12 months, as reported by Puech *et al.* 1997) concluded that most adverse events appeared within the first 3 months of treatment and that the incidence decreased steadily thereafter. More important, no treatment-emergent adverse events developed during long-term treatment. Other adverse events reported in product labeling include headache, constipation, dizziness, insomnia, hot flushes, hyperhidrosis, and vomiting (Forest Pharmaceuticals 2009).

The adverse event profile of levomilnacipran is similar to that of milnacipran and basically relates to noradrenergic mechanisms. Common side effects include hyperhidrosis, increased heart rate, elevation of blood pressure, urinary hesitancy, constipation, and nausea. These effects are generally of low intensity and seldom lead to discontinuation. The QTc interval remains unaltered at all therapeutic dosages (40-120 mg/day) and is not prolonged to a clinically significant extent at a dosage of 300 mg/day (Asnis and Henderson 2015).

Drug-Drug Interactions

Serotonin syndrome, a serious and potentially lethal pharmacodynamic interaction, can result if milnacipran, levomilnacipran, or duloxetine is taken concomitantly with a monoamine oxidase inhibitor or another serotonergic drug. To avoid this catastrophic outcome, a monoamine oxidase inhibitor must not be initiated until at least 5 days after duloxetine, milnacipran, or levomilnacipran has been discontinued. A longer elimination period than that expected from plasma half-life is recommended, because brain elimination generally lags behind plasma elimination. At least a 14-day washout of monoamine oxidase inhibitors must be respected before any SNRI is started.

Use of a serotonin reuptake inhibitor antidepressant with an antiplatelet or anticoagulant drug may potentially increase the risk of bleeding due to the antidepressant's effect on the release of serotonin from platelets.

Duloxetine

Inhibitors of CYP1A2, such as ciprofloxacin, increase plasma levels of duloxetine, and concomitant use may require that duloxetine dosages be reduced or that duloxetine be discontinued. When duloxetine is coadministered with a CYP2D6-inhibiting agent of moderate potency, such as bupropion or diphenhydramine, duloxetine levels may increase. However, such alterations in duloxetine levels are in general not clinically significant.

Duloxetine does not inhibit or induce the activity of the CYP1A2, CYP2C9, or CYP3A4 systems. It does, however, moderately inhibit the activity of the CYP2D6 isoenzyme. If duloxetine is coadministered with a medication metabolized by CYP2D6, clinicians should prescribe dosages that are approximately half those usually recommended for the concomitant medication. Duloxetine does not potentiate the psychotropic effects of ethanol or benzodiazepines.

Milnacipran and Levomilnacipran

If levomilnacipran extended-release capsules are coadministered with agents that are strong CYP3A4 inhibitors (e.g. ketoconazole, clarithromycin, ritonavir), the dosage should not exceed 80 mg once daily (Allergan 2019). Because milnacipran and levomilnacipran are not highly metabolized by CYP pathways, they do not participate in pharmacokinetic drug-drug interactions.

Conclusion

At their minimum effective dosages, duloxetine (60 mg/day) and milnacipran (100 mg/day) potently block the reuptake of serotonin and norepinephrine, respectively. In the case of milnacipran, a 100-mg daily dosage produces suboptimal platelet serotonin reuptake inhibition.

Duloxetine, at its maximum recommended dosage (120 mg/day), and milnacipran, at the upper end of its therapeutic range (200 mg/day), are dual reuptake inhibitors. Consequently, none of the SNRIs currently available can be considered equal reuptake inhibitors. They all show efficacy in the treatment of depression and pain syndromes, with emerging evidence also suggesting a potential role for duloxetine in the treatment of stress urinary incontinence and GAD.

Duloxetine, milnacipran, and levomilnacipran are generally well tolerated, with most adverse effects occurring early in treatment, being mild to moderate in severity, and having a tendency to decrease or disappear with continued treatment.

Either duloxetine or levomilnacipran may be used as a first-line treatment for depression, because these medications are not toxic in overdose, and they can be used at a therapeutic dosage from treatment initiation onward with minimal side effects. Consequently, these drugs may be beneficial in patients whose symptoms have been unresponsive to treatment with SSRIs and/or norepinephrine reuptake inhibitors, provided that they are taken at dosages at the upper end of the therapeutic range.

CHAPTER 21

Ketamine and Esketamine

David S. Mathai, M.D.
Sanjay J. Mathew, M.D.

History and Discovery

Ketamine emerged from the exploration of phencyclidine derivatives suitable for anesthetic use in humans, and its discovery in 1962 is attributed to Parke-Davis and Dr. Calvin Lee Stevens, a professor of organic chemistry at Wayne State University (Domino *et al.* 1965). Following approval by the FDA in 1970, the drug was used as a battlefield anesthetic for American soldiers during the Vietnam War (Jansen 2000). Early clinicians also recognized ketamine's psychoactive and antidepressant properties (Collier 1972; Domino *et al.* 1965; Lilly 1972; Reier 1971), which led to preliminary psychiatric applications of the drug as an adjunct to psychotherapy in various clinical and research populations (Fontana and Loschi 1974; Grof 1980; Khorramzadeh and Lotfy 1973, 1976; Roquet and Favreau 1981; Sappington *et al.* 1979). However, these same properties contributed to increasing reports of nonmedical use over the next several decades, resulting in federal government classification of ketamine as a Schedule III controlled substance in August 1999 (Ahmed and Petchkovsky 1980; Graeme 2000; Shomer 1992). Ketamine abuse is prevalent internationally, especially in parts of Asia, where it has been considered a large-scale problem (Liao *et al.* 2017). Nonmedical use of ketamine also appears to have doubled in the United Kingdom in the past decade but has decreased or stabilized in other regions (United Nations 2021).

Medically, ketamine continues to be used as a general anesthetic in specific populations, as an analgesic for pain unresponsive to standard treatments, and for off-label use in neurology (Persson 2013). Psychiatric interest in ketamine was revived after positive findings from the first randomized controlled trial (RCT) using ketamine for the treatment of depression (Berman *et al.* 2000) and a larger replication study (Zarate *et al.* 2006). Subsequent trials of ketamine and esketamine--an isomeric form of ketamine--confirmed these findings, culminating in FDA approval and legitimization of esketamine as an antidepressive and antisuicidal agent. Other psychiatric applications of ketamine are currently an area of intense investigation and encompass its use in refractory anxiety, OCD, PTSD, disordered eating, substance use disorders, and as an adjunct to psychotherapy.

At the time of this writing (June 2023), ketamine hydrochloride (Ketalar) injection was available as a sterile solution in vials, at three different concentrations: 10 mg/mL, 50 mg/mL, and 100 mg/mL. Dilution, injection, infusion, and drug compatabilities are described in the product labeling, which must be consulted during preparation (PAR Pharmaceuticals 2021). Generic equivalent products are available for all three ketamine hydrochloride concentrations. Esketamine nasal spray (Spravato) is provided in kits, one kit for each product strength (e.g., a 56-mg dose kit and an 84-mg dose kit); no generic equivalent product is available at present (Janssen Pharmaceuticals 2019).

Structure-Activity Relations

Ketamine (2-[2-chlorophenyl]-2-[methylamino]cyclohexanone) is an arylcycloalkylamine compound that is structurally similar to phencyclidine and cyclohexylamine (Figure 21-1). The freebase form of ketamine is highly lipid soluble and is commercially available as an aqueous preparation of the hydrochloride salt. Ketamine is a chiral compound that exists pharmaceutically as a racemic mixture of *(S)*-ketamine (esketamine) and *(R)*-ketamine (arketamine) enantiomers.

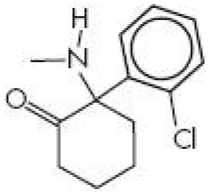

FIGURE 21-1. Chemical structure of ketamine.

Pharmacological Profile

Ketamine has high lipid solubility and low plasma protein binding. It undergoes biotransformation in the liver to norketamine, its primary active metabolite. Approximately 90% of ketamine is excreted in the urine in metabolite form with minimal clearance of unchanged drug, and another 5% undergoes fecal excretion (Clements *et al.* 1982). Ketamine has a wide therapeutic index and has been shown to have a low risk of lethal overdose (Green *et al.* 1999). Its main pharmacological action is on glutamate as an open-channel, nonselective *N*-methyl-D-aspartate (NMDA) receptor antagonist.

Pharmacokinetics and Disposition

Ketamine can be administered by oral, intravenous, intramuscular, subcutaneous, intranasal, epidural, transdermal, intra-articular, and sublingual routes (Kotlinska-Lemieszek

and Luczak 2004). When given orally, ketamine undergoes extensive hepatic biotransformation (via *N*-demethylation by cytochrome P450 [CYP] isoenzymes 3A4, 2C9, and 2B6) into norketamine, the drug's major metabolite. With oral administration of ketamine, norketamine has lower potency than the parent drug but higher plasma levels than those produced when ketamine is given intramuscularly (Grant *et al.* 1981). Hydroxynorketamine, a secondary metabolite also found at high levels soon after administration of ketamine, may play a role in the extended clinical responses that persist after ketamine has been metabolized (Paul *et al.* 2014; Singh *et al.* 2014). Ketamine undergoes renal elimination, and dehydronorketamine is the inactive metabolite that is predominant in urine (Sinner and Graf 2008). The oral bioavailability of ketamine is 17%-20%; bioavailability for other routes is as follows: 25%-50% for intranasal, 30% for sublingual, 30% for rectal, 93% for intramuscular, and approximately 99%-100% for intravenous (Clements *et al.* 1982; Quibell *et al.* 2015). Peak plasma concentrations are reached within 30-60 minutes of oral administration, 5-15 minutes of intramuscular injection, and 1 minute of intravenous injection (Paul *et al.* 2014). Ketamine is rapidly distributed to highly perfused tissues, including the brain, with a distribution half-life of approximately 10-15 minutes and an elimination half-life of 2-2.5 hours (Domino *et al.* 1984). The half-lives of ketamine metabolites are longer than that of the parent drug, measuring 5.3 hours and 6.9 hours for norketamine and dehydronorketamine, respectively (Hijazi *et al.* 2003).

Mechanism of Action

Ketamine is a dissociative anesthetic with analgesic and amnesic properties (Curran and Morgan 2000). The mental state produced by ketamine was originally classified as "dissociative" in an effort to capture the drug's hallucinogenic profile, one that left subjects feeling "disconnected" from their environments (Domino 2010). The term *dissociative* also conveyed the electrophysiological unlinking of thalamoneocortical and limbic systems, thought to be the mechanism by which the drug exerted its primary anesthetic effect on the CNS (Haas and Harper 1992; Jansen 1990; Reich and Silvay 1989).

Ketamine has a complex pharmacological profile, with variable, concentration-dependent affinities for numerous receptors (Alkire *et al.* 2008; Oye *et al.* 1992; Rabiner 2007; Sleigh *et al.* 2014; Smith *et al.* 1981, 1987). Off-target interactions at these receptors are responsible for ketamine's transient cardiovascular, respiratory, and sympathomimetic effects (Domino 2010). Ketamine exerts its primary effect as a voltage-dependent nonselective NMDA receptor antagonist that inhibits the transmembranous flux of calcium and sodium in the presence of the co-agonists glutamate and glycine (Niciu *et al.* 2014). Of ketamine's two enantiomers, *(S)*-ketamine has been shown to have a higher affinity for the NMDA receptor, three-to fourfold greater anesthetic potency, and increased psychotomimetic effects relative to *(R)*-ketamine (Bergman 1999; Jelen *et al.* 2021; Kohrs and Durieux 1998; Wei *et al.* 2020).

It is widely held that ketamine's antidepressant activity occurs via the preferential blockade of NMDA receptors at inhibitory interneurons ("disinhibition hypothesis"), causing disinhibition of pyramidal cells and a burst of excitatory glutamatergic transmission (Duman 2018; Krystal *et al.* 2019; Wei *et al.* 2020). Other proposed NMDA-dependent

mechanisms of action include blockade of spontaneous NMDA receptor-mediated transmission and inhibition of extrasynaptic NMDA receptors by ketamine (Zanos and Gould 2018). However, this central role of NMDA receptors in the treatment of depression has been challenged by preclinical and clinical evidence--that other NMDA receptor antagonists have failed to replicate ketamine's efficacy, for instance (Wei *et al.* 2020; Yang *et al.* 2019). Therefore, mechanisms independent of NMDA receptor inhibition have also been proposed to mediate ketamine's antidepressant action and may include the role of active metabolites, such as hydroxynorketamine (Zanos *et al.* 2016).

Convergent downstream mechanisms and neurotrophic signaling cascades have been implicated in ketamine's antidepressant effects (Deyama and Duman 2020; Wei *et al.* 2020; Yang *et al.* 2019; Zanos and Gould 2018). Relevant and interdependent signaling changes include activation of the non-NMDA glutamate a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor, induction of mammalian target of rapamycin signaling, upregulation of brain-derived neurotrophic factor, and resultant synaptic modeling consistent with existing neuroplasticity-related theories of depression (Price and Duman 2020). Although ketamine is known to interact with the opioid system, the clinical relevance of this effect has been debated and warrants further study (Marton *et al.* 2019; Williams *et al.* 2018, 2019; Yoon *et al.* 2019; Zhang and Hashimoto 2019).

Future mechanistic research about ketamine will benefit from novel and integrated approaches to investigation. Some have argued for greater emphasis on circuit-level activity and conceptualizations of ketamine with more nuance than its action at a single, broadly distributed receptor (Heifets and Malenka 2019; Ionescu *et al.* 2018). Initial data suggest that ketamine may alter belief-updating cognitive processes that are thought to maintain certain forms of psychopathology, such as treatment-resistant depression (Bottemanne *et al.* 2022). Furthermore, there has been renewed interest in the relationship between subjective drug experience and treatment efficacy (Ballard and Zarate 2020; Breeksema *et al.* 2023; Kadriu *et al.* 2021; Mathai *et al.* 2020, 2022, 2023; Sumner *et al.* 2021), which appears important for other highly psychoactive therapies such as 3,4-methylenedioxymethamphetamine and psilocybin (Breeksema *et al.* 2020; Vollenweider and Preller 2020).

Indications for and Efficacy of Ketamine

For details on esketamine indications and efficacy, see the later section "Esketamine."

Approved Indications

Anesthesia

Ketamine gained FDA approval in 1970 for the following indications: 1) as the sole anesthetic agent for diagnostic and surgical procedures that do not require skeletal muscle relaxation, 2) for induction of anesthesia before administration of other general anesthetic agents, and 3) to supplement low-potency anesthetic agents, such as nitrous oxide (PAR Pharmaceuticals 2021). Ketamine was an attractive drug for these indications because of its potent anesthetic properties and its safety profile, characterized by a large therapeutic window and low risk of respiratory depression. Recommended dosages for induction of anesthesia are 6.5-13.0 mg/kg intramuscular and 1.0-4.5 mg/kg intravenous, with alternative off-label recommendations for situations that involve administration of adjuvant drugs (Gropper 2019). For maintenance of anesthesia, the manufacturer recommends administering one-half to the full induction dose *or* a continuous infusion of 0.1-0.5 mg/minute of ketamine; however, clinical studies have suggested that higher dosages may be needed to maintain an adequate concentration for anesthesia (White *et al.* 1982). Although only the racemic mixture of ketamine is marketed for this indication in the United States, *(S)*-ketamine was approved in Europe in 1998 and is available in a number of European Union countries for induction and maintenance of general anesthesia, supplementation of local anesthesia, and analgesia in emergency medicine.

Off-Label Applications

Sedation, Analgesia, and Use in Neurology

Various laboratory and clinical studies suggest the utility of ketamine for sedation, analgesia, and improved postoperative outcomes (Adam *et al.* 2005; Green *et al.* 2011; Hocking and Cousins 2003; Menigaux *et al.* 2000; Remerand *et al.* 2009; Zakine *et al.* 2008). Substantial evidence indicates that subanesthetic doses of ketamine are effective in the management of acute postoperative pain, safely reducing opioid requirements during the first 48 hours after surgery and, to a lesser extent, decreasing postoperative nausea and vomiting (Brinck *et al.* 2018). Although there has been some initial support for the use of ketamine for short-term relief of chronic noncancer (e.g., neuropathic, ischemic, fibromyalgia) pain (Michelet *et al.* 2018; Orhurhu *et al.* 2019), more definitive conclusions have been limited by inadequate long-term clinical efficacy and safety data (Bell and Kalso 2018; Cohen *et al.* 2018; Tran and McCormack 2020). A review of ketamine as an analgesic for phantom limb pain was similarly inconclusive (Alviar *et al.* 2016). RCT data (Schwartzman *et al.* 2009; Sigtermans *et al.* 2009) hint at ketamine's benefit in complex regional pain syndrome type 1 at a variety of dosages and routes of administration; however, larger reviews (Azari *et al.* 2012; Zhao *et al.* 2018) suggest that stronger evidence (drawn from larger studies that include data on unsuccessful trials) is needed before ketamine can be recommended for such usage. The evidence for ketamine as an adjuvant for cancer pain has also been explored but is considered inconclusive at this time (Bell *et al.* 2017; Jonkman *et al.* 2017). Neurological applications of ketamine under investigation include its use for migraines, for seizures, and as a neuroprotective agent (Pribish *et al.* 2020).

Relief of Acute Depression and Suicidal Ideation

Multiple meta-analyses have confirmed ketamine's acute antidepressant effects for patients with depressive episodes associated with major depressive disorder (MDD) or bipolar disorder, including reductions in suicidal ideation (Caddy *et al.* 2014; Lee *et al.* 2015; Marcantoni *et al.* 2020; McIntyre *et al.* 2020; Wilkinson *et al.* 2018; Witt *et al.* 2020). Data have shown rapid improvement of depressive symptoms in up to 71% of patients after administration of a single intravenous dose of ketamine (typically 0.5 mg/kg over 40 minutes), with response seen within hours and peak antidepressant effect typically occurring at 24 hours (Aan Het Rot *et al.* 2012; Lee *et al.* 2015; Mathew *et al.* 2012; Salvadore and Singh 2013). Among patients who showed early benefit (within several days) from a single infusion, the mean duration of response was highly variable.

Studies with varying dosages have demonstrated a dose-response relationship for antidepressant effect, with higher doses (0.5-1 mg/kg) of ketamine associated with greater short-term efficacy (Fava *et al.* 2020) and longer time to relapse (Salloum *et al.* 2020). Notably, treatment-dependent adverse effects may also increase with dosage (McIntyre *et al.* 2021). Although it is not yet known which dosages or routes of administration are optimal, there is currently good support for the efficacy of intravenous, intranasal, and oral formulations of ketamine for depression (McIntyre *et al.* 2020). The evidence for intramuscular ketamine is not as well established, but preliminary data suggest this route may also be a safe, practical, and efficacious alternative (Dore *et al.* 2019; Kheirabadi *et al.* 2020; Loo *et al.*

2016). Variables such as provider experience, clinical infrastructure, patient preference, relative costs, accessibility, and other ethical considerations may further guide clinical decision-making (American Society of Ketamine Physicians, Psychotherapists, and Practitioners 2020; McIntyre *et al.* 2021; Singh *et al.* 2017; Wesley and Bennett 2020).

One strategy for extending ketamine's antidepressant benefit has been that of repeat dosing, although the long-term risks and optimal frequency of multiple administrations are unknown (McIntyre *et al.* 2020; Murrough *et al.* 2013; Rasmussen *et al.* 2013). Notably, one study found that twice-weekly dosing did not appear to confer greater benefit than ketamine given thrice weekly (Singh *et al.* 2016). In a Cochrane Review meta-analysis of 25 double-blind and single-blind RCTs (1,242 participants) comparing intravenous administration of 11 different glutamate receptor modulators with placebo, other active psychotropic drugs, or electroconvulsive therapy in adults with unipolar MDD, only ketamine showed a significant effect in reducing the acute symptoms of depression (Caddy *et al.* 2015). Although other NMDA antagonists and glutamatergic modulators have demonstrated antidepressant properties, none to date have replicated ketamine's therapeutic profile and clinical efficacy (Henter *et al.* 2018; Pochwat *et al.* 2019).

Results from individual studies and larger reviews confirm that ketamine achieves a rapid reduction in suicidal ideation, lasting up to 7 days from previous administration and extended by repeat dosing (Domany *et al.* 2020; Murrough *et al.* 2015; Phillips *et al.* 2020; Witt *et al.* 2020). Of note, limited controlled data are available on ketamine's effects for patients with a more severe risk of suicide, such as patients who have been hospitalized for suicidal ideation or a suicide attempt (Price and Mathew 2015).

Investigative Applications in Psychiatry

Ketamine has been investigated for a number of other psychiatric indications beyond depression. A growing body of evidence suggests that ketamine has value in the treatment of refractory anxiety disorders, including generalized anxiety, social anxiety, and anxiety with comorbid depression or bipolar disorder (Banov *et al.* 2020). These effects extend to OCD and PTSD, which are no longer classified as anxiety-spectrum disorders but are acknowledged to feature anxiety as a significant illness component. In a randomized, placebo-controlled crossover trial of ketamine in unmedicated patients with refractory OCD, participants who received ketamine first

showed significant and rapid antiobsessional effects during the 0.5 mg/kg infusion that persisted until 1 week after infusion, compared with participants who began with placebo saline infusion (Rodriguez *et al.* 2013). A subsequent study of the neurochemical effects of ketamine versus saline infusions using proton magnetic resonance spectroscopy suggests that the therapeutic effect of ketamine in OCD may occur independently of glutamate-glutamine activity (Rodriguez *et al.* 2015). Both single (Feder *et al.* 2014) and repeated (Feder *et al.* 2021) doses of ketamine have been efficacious when compared with midazolam for chronic PTSD in small RCTs. Preliminary data also support the utility of ketamine when combined with the opioid antagonist nalmefene for compulsive behavior in eating disorders (Mills *et al.* 1998).

Subanesthetic dosages of ketamine have also been associated with improved outcome for substance use disorders. Studies of cocaine users have shown that ketamine decreases drug use, reduces craving, and increases motivation for treatment (Dakwar *et al.* 2014, 2017, 2019). Increased abstinence rates have been demonstrated with ketamine for opioid (Jovaisa *et al.* 2006; Krupitsky *et al.* 2002, 2007) and alcohol (Dakwar *et al.* 2020; Krupitsky and Grinenko 1997; Wong *et al.* 2015) dependence. Several of these studies have been embedded in a psychotherapeutic context, including motivational, mindfulness-based, and existentially oriented therapies. Others have more broadly considered the value of a psychedelic framework and flexible treatment paradigms in approaching the psychiatric use of ketamine (Bennett 2019; Bravo *et al.* 2021; Dore *et al.* 2019; Lieberman 2021; Ring *et al.* 2016; Sumner *et al.* 2021). It is important to note that these uses are investigational as of the time of this writing (2023).

Side Effects and Toxicology

Ketamine has a wide margin of safety but may be associated with various adverse reactions. At anesthetic dosages of the drug (1-3 mg/kg), "emergence phenomena"--characterized by a range of psychological manifestations including hallucinations, confusion, delirium, vivid imagery, and a prolonged dreamlike state--have occurred in approximately 12% of patients recovering from anesthesia (Green *et al.* 2011). Of note, it is not clear how such phenomena overlap with and differ from altered states of consciousness associated with the therapeutic benefit of other psychedelic treatments (Johnson *et al.* 2019; Sumner *et al.* 2021). Other common side effects ([?] 10%) of ketamine include transient nystagmus, diplopia, hypertension, tachycardia, respiratory stimulation, nausea, vomiting, and skin inflammation or rash. Less common side effects ([?] 1%) include anorexia, bradycardia, cardiac arrhythmia, hypotension, and respiratory depression. In rare cases ([?] 0.1%), anaphylaxis, sialorrhea, laryngospasm, and cystitis have been reported. Ketamine-induced renal dysfunction, ulcerative cystitis, and abdominal pain seem to be more prevalent in frequent, high-dose users (Curran and Morgan 2000).

At the subanesthetic dosages (0.1-1 mg/kg) used in studies investigating ketamine's analgesic and antidepressant properties, psychotomimetic effects are commonly reported, including symptoms of dissociation, perceptual disturbances, abnormal sensations, depersonalization, and derealization, which peak and resolve within 1-2 hours of drug administration (Short *et al.* 2018). These and other subjective experiences associated with acute ketamine administration have correlated positively

with antidepressant response (Mathai *et al.* 2020; Niciu *et al.* 2018; Sumner *et al.* 2021) but are not thought to be necessary or sufficient for outcome (McIntyre *et al.* 2021). Attention to environment, comfort, adaptability, and other contextual variables may best ensure psychological safety and optimize clinical efficacy when dealing with drug-mediated states of consciousness (Johnson *et al.* 2008; McIntyre *et al.* 2021). Other psychiatric effects associated with ketamine include possible worsening of mood or anxiety, leading to discontinuation of treatment for some patients (Short *et al.* 2018). Ketamine dependence has been reported in the scientific literature, and potential for misuse and addiction may be related to its agonist activity at m opioid receptors or to its dopaminergic effects (Lindefors *et al.* 1997; Liu *et al.* 2015; Sanacora and Schatzberg 2015; Xu and Lipsky 2015).

Dizziness, drowsiness, light-headedness, headache, and blurred vision are common neurological effects reported with subanesthetic doses of ketamine. Therefore, patients are advised to arrange alternative transportation for appointments and to not operate motor vehicles or hazardous machinery without at least one night of sleep following the appointment (McIntyre *et al.* 2021). Some evidence exists for mild, acute cognitive disturbances; these should be considered alongside preclinical data suggesting that ketamine may be neurotoxic in certain contexts, based on timing of administration, dosage given, and extent of exposure (Krystal *et al.* 1994; Malhotra *et al.* 1996; Morgan *et al.* 2004; Newcomer *et al.* 1999; Soriano 2012). Studies of ketamine abusers and rodent models have also pointed to adverse effects on brain structure and function under certain conditions of chronic exposure (Liao *et al.* 2011; Schobel *et al.* 2013; Wang *et al.* 2013). Although more long-term data are needed, no persistent or replicable cognitive impairments have been reported among those receiving ketamine in controlled treatment settings (McIntyre *et al.* 2021).

Nausea is the most commonly reported adverse gastrointestinal effect attributed to ketamine (Short *et al.* 2018). Rare cases of hepatoxicity have also been reported. Genitourinary toxicity is uncommon, although lower urinary tract symptoms may increase with cumulative long-term exposure to ketamine (McIntyre *et al.* 2021). Cardiorespiratory effects, including mild stimulation of the cardiovascular system and respiratory depression, have been consistently demonstrated within psychiatric dose ranges (Riva-Posse *et al.* 2018; Rodrigues *et al.* 2020; Szarmach *et al.* 2019). Increases in heart rate or blood pressure appear dose-dependent but are generally minimal, asymptomatic, and transient. However, because some cases may require antihypertensive treatment or result in palpitations, arrhythmias, chest pain, or hypotension, adequate monitoring and medical support should be available during administration. Cardiac function should be continually monitored for high-risk patients (PAR Pharmaceuticals 2021).

Ultimately, ketamine administration for depression should be provided in settings with expertise in both psychiatric and medical safety (McIntyre *et al.* 2021). Acute side effects commonly occur with ketamine but are largely transient and self-limited. Taken together, these findings suggest that subanesthetic doses of ketamine administered to depressed patients in a controlled setting present a low and acceptable level of risk, although great emphasis must be placed on ongoing clarification of optimal dosage and administration, appropriate patient selection, factors mediating the frequency and severity of adverse effects, abuse potential, and long-term efficacy and safety data.

Drug-Drug Interactions

Drugs such as rifampin and St. John's wort (which are potent inducers of CYP3A4) increase the metabolism and clearance of ketamine--and, to a much greater extent, of norketamine (Mion and Villevieille 2013). Enzyme-inhibiting substances have the opposite effect and include clarithromycin and grapefruit juice (CYP3A4 inhibitors) and ticlopidine (a potent CYP2C19 inhibitor and a weak CYP2B6 inhibitor) (Domino *et al.* 1984). Several studies have also reported ketamine's synergistic effects when administered with other sedatives (Akhavanakbari *et al.* 2014; Eker *et al.* 2011; Hui *et al.* 1995; Lo and Cumming 1975). The clinical relevance of these interactions remains unclear. Though not contraindicated, monoamine oxidase inhibitors, psychostimulants, and other agents with significant hemodynamic activity should be administered with caution when given with ketamine (McIntyre *et al.* 2021). Studies examining whether opioid antagonists interfere with ketamine's antidepressant effect have reported mixed findings (Marton *et al.* 2019; Williams *et al.* 2018). Furthermore, agents that significantly affect glutamate release, such as alcohol, benzodiazepines, and lamotrigine, may theoretically attenuate response to ketamine and therefore warrant further investigation. No absolute drug contraindications exist for ketamine at the time of this writing (2023).

Esketamine

Intranasal esketamine in conjunction with an oral antidepressant is approved by the FDA for adults with treatment-resistant depression and, more recently, for depressive symptoms in adults with MDD with acute suicidal ideation or behavior (Janssen Pharmaceuticals 2019). Regulatory approval has also been granted by the European Medicines Agency and is pending in other parts of the world (McIntyre *et al.* 2021). Although two of three short-term regulatory trials used by the FDA (Studies 3001 and 3005) did not show a statistically significant effect for primary outcome, drug approval was uniquely granted because of the positive results from the remaining short-term trial (Study 3002) and one longer-term randomized withdrawal study (Study 3003) supporting esketamine's efficacy, durability of effect, dosing interval, and safety (Kim *et al.* 2019).

Esketamine carries a black box warning for 1) sedation and dissociation after administration, 2) potential for abuse and misuse, 3) requirement of a Risk Evaluation and Mitigation Strategy (REMS) drug safety program, and 4) increased risk of suicidal thoughts and behaviors in children and young adults taking antidepressants. Information on the REMS program for Spravato is available from the FDA website (www.fda.gov), which hosts a database of all REMS programs and their unique requirements. Patient Medication Guides are also provided as part of the Spravato product labeling (Janssen Pharmaceuticals 2019). Drug dosing involves two phases of administration: induction and maintenance. The first dose (day 1, week 1) is 56 mg, after which the patient receives 56 or 84 mg twice weekly during weeks 1-4 (induction), then 56 or 84 mg once weekly for the following 4 weeks, and then 56 or 84 mg every week or every 2 weeks (maintenance) as needed to maintain individual remission

or response (Janssen Pharmaceuticals 2019). Dosing frequency should be individualized to the least frequent dosing needed to maintain remission/response. Treatment discontinuation is recommended if only minimal response to esketamine is observed after the initial induction phase.

Compared with ketamine, esketamine benefits from FDA approval and robust clinical investigation. However, esketamine and racemic ketamine are thought to share comparable safety profiles (Correia-Melo *et al.* 2020). Importantly, postmarketing data from the FDA Adverse Event Reporting System database signal that serious adverse effects of esketamine may exist, including suicidal ideation and completed suicide (Gastaldon *et al.* 2021). On the basis of these data, combined with evidence of suicides completed on discontinuation of treatment within the esketamine development program, it is recommended that providers carefully monitor psychiatric safety risk during and while transitioning treatment for both ketamine and esketamine (McIntyre *et al.* 2021). No definite conclusions about the relative efficacy of the two drugs can be reached at present, given the heterogeneity of studies and the absence of adequate head-to-head data (McIntyre *et al.* 2020). However, preliminary evidence suggests that ketamine may have superior efficacy and lower dropout rates (Bahji *et al.* 2021; Singh *et al.* 2016). Factors such as cost and access should also be considered in treatment selection.

Conclusion

From its initial use as an anesthetic and analgesic agent, ketamine has evolved as a versatile and consequential drug, uniquely equipped to address a great unmet need in psychiatry. Racemic ketamine and its *(S)*-enantiomer, esketamine, have been established as efficacious treatments for acute depression and suicidal ideation. Other treatment applications appear promising, but for now they remain investigative. Ongoing research is needed to clarify the mechanisms of antidepressant efficacy at subanesthetic dosages of ketamine. Toward this end, early investigations have identified key contributors relevant to ketamine's therapeutic benefit, which include glutamate-dependent and -independent mechanisms, convergent downstream signaling processes, changes in circuit-level activity, and even phenomenological characteristics of acute drug experience. These actions are not mutually exclusive and probably function in a complex and interdependent fashion. Finally, although a growing body of pioneering work supports the safety and tolerability of ketamine, unanswered questions remain, particularly with respect to long-term efficacy and risks. How might we minimize harm and sustain therapeutic benefit? Where does ketamine fit in treatment algorithms? What are predictors of response and individualized success factors? What are important ethical and regulatory considerations? Is ketamine a psychedelic drug? How does ketamine work in conjunction with psychosocial interventions? While we work toward a broader understanding of the drug, ketamine is a powerful tool that relieves suffering today.

CHAPTER 22

Benzodiazepines

David V. Sheehan, M.D., M.B.A., DLFAPA, FACPsych

History and Discovery

Despite adverse publicity and a problematic public image, the most widely prescribed psychiatric medication in the United States over the past two decades is not an antidepressant, an atypical antipsychotic, or a mood stabilizer but the benzodiazepine alprazolam, with more than 48 million prescriptions issued in 2013 (see Grohol 2015; Stahl 2002). There were 92 million prescriptions for benzodiazepines in 2019. Approximately half of those taking benzodiazepines continued taking them for 2 months or more. According to data from a nationally representative survey of 86,186 adults conducted in 2015 and 2016, it is estimated that 30.6 million adult U.S. residents (12.6%) used benzodiazepines in the past year. Of these, 17% reported misuse, with 51% of individuals between 18 and 25 years and 4% of those 65 years or older reporting misuse of benzodiazepines in the past year (Maust *et al.* 2019).

The first benzodiazepine, chlordiazepoxide, was patented in 1959. Diazepam was introduced in 1963, and numerous derivatives of this drug have since been introduced into the market. The triazolobenzodiazepine alprazolam was introduced in 1981 and revolutionized the treatment of anxiety disorders when it was shown to be effective in the treatment of panic disorder (Chouinard *et al.* 1982; Sheehan *et al.* 1982). It was the first benzodiazepine to be approved by the FDA for the treatment of panic disorder. Since then, clonazepam, another high-potency benzodiazepine, also has received approval from the FDA for the treatment of panic disorder.

Benzodiazepines were widely prescribed in the 1960s, 1970s, and 1980s for pathological anxiety by psychiatrists, family practitioners, and internists who knew the drugs were effective and safe when compared with prior anxiolytic medications such as the barbiturates and meprobamate. However, since the 1990s selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have displaced benzodiazepines as the clinician's first choice for the treatment of anxiety disorders (Kramer 1993). The SSRIs and SNRIs are safer and better tolerated than the tricyclic antidepressants and have been shown to be efficacious in several different anxiety disorders. In addition, they do not have the propensity to cause dependence, withdrawal, or alcohol interaction, or the abuse potential, of the benzodiazepines.

Despite their drawbacks, benzodiazepines have continued to be widely prescribed, both as an adjunctive treatment with an SSRI or SNRI and as the primary treatment for a patient with no response or only a partial response to the SSRI or SNRI. As a result, there has been only a small decline in benzodiazepine prescribing since the SSRIs and SNRIs became available (Uhlenhuth *et al.* 1999). One benzodiazepine user in four takes the drug for a year or longer. Among individuals using a benzodiazepine as a hypnotic, 14% reported long-term use (Balter 1991). Rates of use increase with age, from 2.6% among individuals ages 18-35 years to 8.7% among those ages 65-80 years (Olfson *et al.* 2015). In recent years, there has been a shift to greater use of short-half-life benzodiazepines.
